## **ABSTRACT**

This thesis investigated the suitability of wireless, unattended ground sensor networks for military applications. The unattended aspect requires the network to self-organize and adapt to dynamic changes. A wireless, unattended ground sensor network was prototyped using commercial off-the-shelf technology and three to four networked nodes.

Device and network performance were measured under indoor and outdoor scenarios. The measured communication range of a node varied between three and nineteen meters depending on the scenario. The sensors evaluated were an acoustic sensor, a magnetic sensor, and an acceleration sensor. The measured sensing range varied by the type of sensor. Node discovery durations observed were between forty seconds and over five minutes. Node density calculations indicated that the prototype was scalable to five hundred nodes. This thesis substantiated the feasibility of interconnecting, self-organizing sensor nodes in military applications. Tests and evaluations demonstrated that the network was capable of dynamic adaptation to failure and degradation.

## EXECUTIVE SUMMARY

The evolution of integrated circuit technology, wireless communications, and data networking makes wireless, unattended sensor networks practical technology for military applications. This evolution continues to decrease the size, weight and cost of sensors and increase their fidelity and utility. To be a viable technology, wireless, unattended ground sensor networks require sensor nodes capable of interconnection and self-organization. The sensor nodes must also dynamically adapt to failure, degradation and mobility. Many of the technological risks associated with wireless, unattended sensor networks are resolved; however, many technological challenges remain. System-level research is required to mitigate these challenges and to design prototypes for military applications.

The objective of this thesis was to undertake a system-level evaluation of node and network performance. A node is a device equipped with a suite of sensors and a transceiver. Node and network performance were evaluated in a variety of scenarios applicable to both military and civilian deployments. Specific performance objectives were to measure the communication range and the sensing range of nodes, the network organization, and network traffic. The evaluated scenarios included outdoor, urban and indoor environments.

The characteristics of wireless sensor networks, types of sensors, the IEEE standard 802.15.4 for wireless personal area networks, and TinyOS operating system were discussed. A network prototype was designed based on these characteristics. The network architecture was comprised of a cluster of three to four nodes. The node's communication range, which varied from three to nineteen meters, was measured for indoor and outdoor scenarios. A sensor's range and sensitivity were measured by forming scenarios based on the operating characteristics unique to each type of sensor. The specific types of sensors evaluated were an acoustic sensor, a magnetic sensor, and an acceleration sensor. The network performance aspects of node discovery and network topology were evaluated. The network was capable of self-organization and was responsive to topology changes caused by failure, degradation, and mobility.

The characteristics and performance of wireless, unattended ground sensor networks demonstrated their suitability for military applications. The system-level evaluation of device communication and sensing range, along with network performance detailed in this thesis, provide a method to assess the military applicability of wireless, unattended ground sensor networks.

## **I. INTRODUCTION**

The documents shaping our national military strategy indicate the requirement for improved sensor networks. Joint Vision 2020 [1] recognizes the role of sensor networks in full-spectrum dominance by enhancing the ability for dominant maneuver and precision engagement. Sea Power 21 [2] mandates persistent intelligence, surveillance and reconnaissance operations using autonomous sensors with long dwell times. These publications led toward the concept of an Expeditionary Sensor Grid [3]. The grid characteristics include real time sensor coverage, fully networked nodes with density in the hundreds to thousands of nodes, and low power devices with a battery life of months or years. The grid would utilize sensors that are plug and play to allow for seamless fusion of sensor data.

The development of wireless, unattended ground sensors offers the opportunity to fulfill these visions and mandates. Previously, wireless sensors were not commercially viable as they required constant monitoring and substantial processing. The evolution of integrated circuit technology, wireless communications, and data networking has made wireless unattended sensor networks practical. Improvements in sensor network technology continue to decrease the size, weight and costs of sensors and increase their resolution and utility. Research efforts have minimized the technological risks associated with wireless sensor networks; however, many technological challenges associated with military applications remain. [4]

### **A. OBJECTIVE**

The objective of this thesis was to provide a system-level test and evaluation of node and network performance measurements in a variety of military scenarios. Specific performance metrics include the radio and sensor range, and the network organization and traffic.

Based on the IEEE 802.15.4 standard, a prototype sensor network was developed. The network architecture was comprised of a cluster head with three networked nodes. The radio range of the devices was measured for several scenarios. The sensor's range

and sensitivity were measured based on the device's operating characteristics. The network performance was evaluated for node discovery, number of nodes, network topology, and network routing.

## **B. ORGANIZATION**

The thesis is organized as follows. Chapter II provides an overview of wireless sensor networks: architecture, layering and network components. The chapter concludes with a discussion of the operating characteristics of sensors. Chapter III briefly describes the differences among the IEEE 802.15 family of standards. Detailed discussion of the IEEE 802.15.4 standard for low-rate, wireless personal area networks is provided. The details of prototype network design are also included. The performance of a prototype was evaluated in this thesis. Chapter IV provides an overview and measured results from the variety of tests and experiments conducted to evaluate the performance. The experiments and tests were designed to measure network and sensor performance in a variety of scenarios. Chapter V provides conclusions and recommendations.

## **II. WIRELESS SENSOR NETWORKS**

Wireless sensor networks consist of devices that combine the functionality of sensing, computation and communication into a single device capable of self-organization and inter-device connectivity. Wireless sensor networks can be used in a number of military and civilian applications. In most of these applications of interest, self-organization of the underlying wireless nodes, size of the node and energy consumption are key design issues. This chapter provides an overview of wireless sensor networks, their characteristics, and their network architecture and connectivity. Sensor network protocols are discussed, followed by methods for network localization. The challenges of security, energy management, synchronization and tracking are discussed. This chapter concludes with a discussion of a variety of sensors.

### **A. CHARACTERISTICS OF A NETWORK NODE**

A sensor node is an interconnected device capable of autonomous organization. Autonomous organization requires nodes to self-govern their arrangement into working order. The nodes have the ability to sense the physical environment and communicate this information to a designated base station, cluster head or node. A sensor node possesses the following distinguishing characteristics. The network is typically highly distributed, and the nodes are wireless and lightweight. These distinguishing characteristics can be categorized as low power, small form factor, self-organization and concurrency of operation, and diversity in design and use. [5]

A sensor node must operate in low power modes to extend battery life. The battery life requirement is application specific; typically three to five years is desirable. To achieve this level of performance, the sensor node must execute all functions quickly and turn itself off. The size of the battery is the governing factor in producing a device with a small form factor. These reductions in size and power mandate strict and effective system design. [5, 6]

The networked sensor's ability to self-organize allows for unattended operation. A sensor node capable of interconnecting and adapting to dynamic network topology im-

proves reliability, scalability and fault-tolerance. Self-organization improves ease of installation; therefore, the ability to self organize is designed in the software. [6, 7]

The sensor node must perform critical operations concurrently. One of the concurrent operations is data gathering. Data gathering is the propagation of requests for information and data dissemination. The other concurrent operation is the reporting procedures. This is the collection of data at an aggregate location. The concurrency of these two operations burdens the network with the simultaneous capture of sensor data and streaming of data onto the network. The reason for concurrent operations is that data may be received from another node and node design typically provides little storage capacity. The limited storage capacity makes buffering an unattractive alternative. [5, 8]

## **B. SENSOR NETWORK ARCHITECTURE**

The requirements of sensor nodes mandate a strict and effective system design. This design criterion also governs the interconnection of sensors. The interconnection of sensors forms the network topology or architecture. The characteristics of self-organization and low power operation govern design of the network architecture. Sensor network architectures can be classified into two broad categories of “layered architecture” and “clustered architecture”. These two architectures and their associated characteristics are described next.

### **1. Layered Architecture**

In a layered architecture, a network consists of a base station (BS) with multiple node layers. Grouping nodes with identical hop count to the base station forms a node layer. An illustration of layered sensor network architecture is shown in Figure 1. The base station acts as an access point or gateway to the wired network. The base station gathers and disseminates data. The nodes of each layer form a wireless backbone to establish connectivity. The network participants could access the network using handheld transceivers. These transceivers are distinguished by their human interface and would be similar to Personal Digital Assistants (PDAs). This type of transceiver would connect to the wireless backbone formed by the layered nodes. The architectural advantage allows each node short communication distances and the ability to employ low transmission power. [8]

**Figure 1. Layered Architecture Illustrating Three Node Layers.**  
(After Ref. [8].)

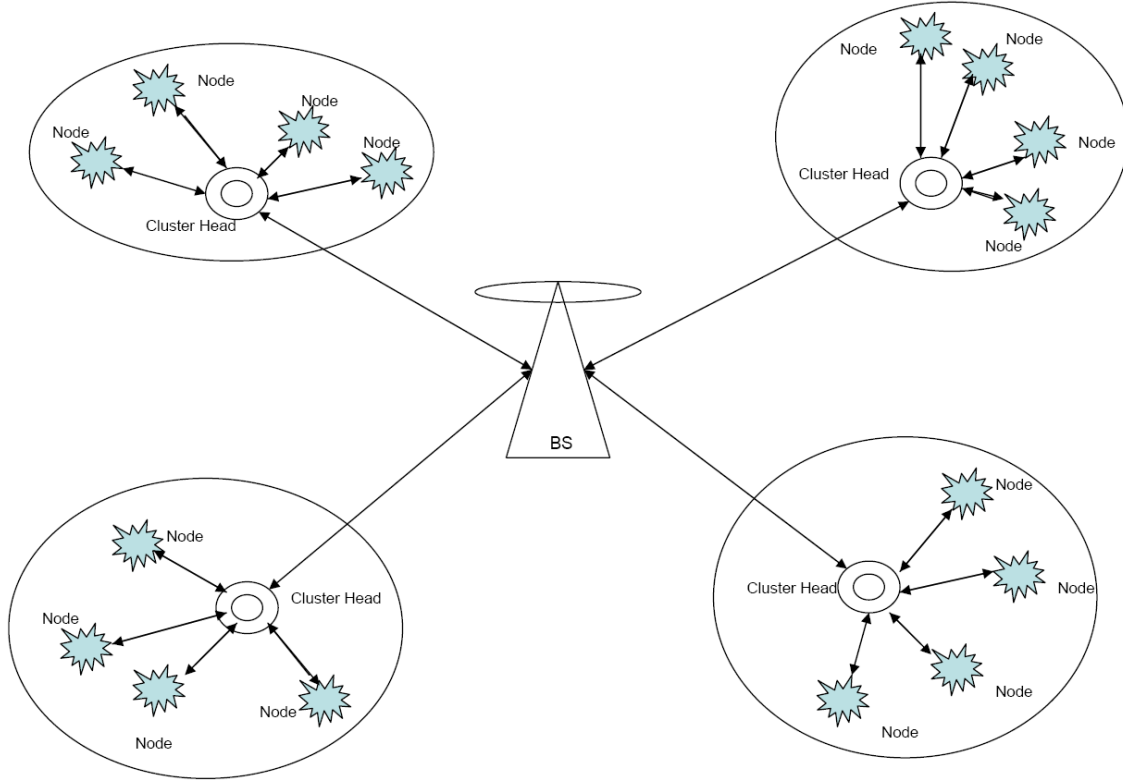

## 2. Clustered Architecture

A clustered architecture consists of a cluster head, or Personal Area Network (PAN) coordinator, which organizes the sensor nodes, communicates for them to the BS and typically interfaces with another network. This architecture is well suited when data fusion is required. The cluster head fuses data gathered by member nodes and transmits the resulting information to the base station. An illustration of a clustered architecture is shown in Figure 2. In order for clustered networks to achieve the self-organization, the cluster formation and election process must be an autonomous, distributed process. This is achieved through network layer protocols, such as Low-Energy Adaptive Clustering Hierarchy (LEACH). [8, 9]

A set of protocols for complete implementation of a layered architecture is described as a Unified Network Protocol Framework (UNPF). Three operations are integrated into the protocol structure of UNPF: network initialization and maintenance, Medium Access Control (MAC) and routing protocols. The BS broadcasts an identifying beacon on a common control channel. All nodes that receive the beacon broadcast their signal at their low power setting along with their own identification. Those nodes that the BS can directly communicate with form layer one. All nodes then transmit a beacon sig-

nal again. Nodes that receive this beacon again broadcast their signal at their low power setting along with their own identification. Thereby, the nodes of layer one establish layer- two nodes by recording the identification of the nodes with which they can communicate. The iterations continue until all nodes are identified with a layer. Thereafter, a periodic beacon refreshes the architecture. [8]

**Figure 2. Clustered Architecture Illustrating Cluster Head Establishment. (After Ref. [8].)**

LEACH operates in two phases, setup and steady state. During the setup phase, LEACH minimizes energy dissipation by randomly selecting and periodically reselecting nodes as cluster heads. This way, the high energy consumption experienced by cluster heads is distributed throughout the network, thereby assuring that all cluster heads eventually expend equal energy. After selection, the cluster heads advertise their selection to all network nodes. The nodes in turn associate themselves with the nearest cluster head

based on the received signal strength of the selection advertisement. A TDMA schedule is then assigned for node communication. The steady-state phase is long in comparison to the setup phase in order to minimize the overhead of cluster formation. Data transmission takes place during the steady-state phase based on the TDMA schedule established during setup. Energy is conserved by local processing and data aggregation at the cluster head. [9]

This section described the two broad classifications of network architecture as layered and clustered. A technique for establishing each classification was discussed. This discussion was designed to assist the reader in gaining perspective into how the characteristics of self-organization and low power operation govern design of the network architecture. A discussion of protocols for a typical wireless, sensor network follows.

### **C. SENSOR NETWORK PROTOCOLS**

The communication functionality of a sensor network node follows layered protocol architecture. Figure 3 describes the typical layered protocol stack of a sensor network node. The application layer provides mechanisms for analog-to-digital conversion. The network layer is responsible for seamless transfer of information, and the data link layer provides fair access and is responsible for error-free transmission. The physical layer provides a means of sending and receiving a bit stream. In the following sections, the functions of the different layers are discussed, and the main design issues are highlighted.

#### **1. Physical Layer**

Wireless sensor networks are designed for low bit rates. The lower rate supports the essential characteristics of longer battery life and self-organization. Wireless sensor networks could conceivably communicate using radio or infrared techniques; the focus here is on radio techniques. Some of the proposed radio frequency (RF) techniques are PicoRadio, Wireless Integrated Network Sensors (WINS), and the IEEE 802.15 Standards for Wireless Personal Area Networks (WPAN). PicoRadio [10] employs ultra-wide band at the physical layer. WINS [11] employs spread spectrum techniques in unlicensed Industrial, Scientific, and Medical (ISM) frequency bands. [12]

The IEEE 802.15 family of standards provides three physical layer options. Bluetooth is the basis for IEEE 802.15.1 standard. The IEEE 802.15.3 is a high-bit-rate WPAN and IEEE 802.15.4 is a low-bit-rate WPAN. [13]

**Figure 3. Protocol Stack for Typical Sensor Network (After Ref. [14].)**

## **2. Data Link Layer**

The data link layer provides fair access to the physical layer and is responsible for error-free transmission (see Figure 3). Medium Access Control (MAC) is a sub-layer of the data link layer. This section provides a brief discussion of challenges and broad categories associated with sensor network MAC protocols followed by a description of several widely used MAC protocols.

The medium access control protocol is an intermediary between the physical layer and the upper layers. Typically, on the upper layer side, it coordinates with the logical link control, which in turn interfaces with the network layer. A typical sensor network MAC protocol undertakes the functions of fair sharing of the physical medium by multi-

ple users and efficient utilization of the data rate. The MAC protocol supports the physical layer by optimizing the data frame size and frequency of transmission. The MAC protocol provides energy management, flow and error control, timing and synchronization.

Sensor network MAC protocols may be categorized into three types: fixed allocation, demand-based, and contention based. Fixed-allocation protocols share the channel through a predetermined assignment. They are appropriate for networks that continuously observe and propagate deterministic data traffic. Fixed-allocation protocols lead to inefficiencies when the channel requirements of each node are time-varying. A time-varying channel requires demand-based protocols, which allocate channel space based on node demand. Although additional overhead is required to reserve the channel, they are well suited for variable rate traffic. In contention-based protocols, nodes compete for channel access. If the channel is busy, each node waits a random amount of time before attempting to access the channel again. Contention-based protocols are suitable for sensor networks that generate non-deterministic traffic. Time sensitive traffic may experience delay and traffic collisions are an issue. [8]

Some of the popular sensor network MAC protocols in these categories are: Self Organizing MAC for Sensor Networks (SMACS), Eavesdrop and Register (EAR), Hybrid TDMA/FDMA, and CSMA-Based.

SMACS and EAR work together to handle network initialization and mobility. SMACS is a distributed protocol for network establishment and link layer association. SMACS handles discovery of neighbor nodes and channel assignment concurrently. The EAR protocol provides integrated linking of nodes under moving and motionless conditions. The protocol utilizes certain mobile nodes working together with static nodes to provide connections. Mobile nodes listen for control signals to update its list of neighbors. The mobile nodes dominate connections and terminate links degraded by mobility. EAR independently handles mobility, an aspect transparent to SMACS. [15]

The hybrid TDMA/FDMA scheme is centrally regulated and assumes that nodes converse straight to a nearby base station. A TDMA scheme minimizes delay at the cost of time synchronization. An FDMA scheme provides the minimum bandwidth required

for each link. The hybrid scheme uses an ideal number of channels to diminish overall power expended and depends on the proportion of transmitter to receiver power expenditure. If the transmitter expends greater power, a TDMA scheme is desired since it can be turned off during idle time slots. When the receiver consumes greater power, the scheme favors FDMA. [16]

For point-to-point, random traffic flow, traditional CSMA-based MAC schemes are better suited. These protocols adapt well to the variable, but periodic and correlated traffic of sensor networks. CSMA-based MAC protocols are contention-based and are designed mainly to increase energy efficiency and maintain fair access. Woo and Culler [16] describe a CSMA-based MAC protocol for sensor networks. Energy efficiency is achieved by constant sensing periods. Collisions are avoided and binary exponential back-off introduces random delay in order to avoid repeated collisions caused by the synchronized nature of networked sensors. The MAC protocol also controls the rate of data originating at the node so that nodes closer to the BS do not dominate traffic flow. [8, 17]

This section presented a description of the design challenges and types of MAC protocols. Several widely studied protocols were briefly discussed.

### **3. Network Layer**

The network layer controls network operations. It has the traditional function of routing packets. The distributed nature of sensor networks makes routing a challenge, which is compounded by the low power operation of network nodes.

Routing protocols determine how data flow through the network from source to destination. A number of routing techniques including flooding, gossiping and rumor routing are briefly described below.

#### ***a. Routing Techniques for Layered Architecture***

Routing techniques for layered architecture include flooding, gossiping, and rumor routing. “Flooding” is one routing technique in which rebroadcast occurs until maximum destination node is reached or a maximum hop count is achieved. While the technique avoids complexity, it does not account for duplication of received packets, overlap of sensor coverage or available node energy. A modified version is “gossiping” in which a packet is not broadcast but rather transmitted to a randomly chosen neighbor.

This avoids the problem of duplication but does not offer reliability. “Rumor” routing uses an agent to circulate through the network recording the shortest path to events encountered. [8]

***b. Routing Techniques for Clustered Architecture***

The above techniques are predominant in layered architecture networks, which employ a base station. When the sensor nodes themselves are the destination (peer-to-peer), rather than all queries arising from the BS, directed diffusion is a useful protocol. The “directed diffusion” routing protocol employs interest gradients in which the destination specifies the data-rate requirement, raising or lowering the data rate based on the sensors’ ability to report on the destination’s interest. [19]

When a sensor network is peer enabled routing approaches include Sensor Protocols for Information via Negotiation (SPIN), Cost-Field approach, and Geographic Hash Table (GHT). “SPIN” overcomes the weaknesses of flooding through negotiation and resource versatility. Negotiation reduces duplication and overlap prolonging network lifetime. The “Cost-Field” approach uses cost as the minimum cost from the node to the destination – the cost of the optimal path. Packets contain a cost-so-far field. Each intermediate node updates the cost-so-far field and continues to execute the algorithm. The “Geographical Hash Table” (GHT) compiles keys into geographic coordinates and maintains the key and value at the sensor node nearest the hash value. The consistency of mapping assures data is routed correctly. The data is distributed among nodes in a scalable and balanced method. [20–22]

Because of power constraints, routing protocols designed for sensor networks are not isolated at the network layer. The protocols gaining widest acceptance consider efficiencies at each layer of the protocol stack shown in Figure 3. LEACH [9] is one such protocol.

Another protocol whose design considers energy efficiency techniques within each of the layers is XMesh. The “XMesh” protocol evolved from the initial Surge-Reliable and Mint Route protocols developed by Hill and Woo [23]. XMesh features include self-organizing, self-healing, low-power listening and time synchronization. It can provide quality of service through link-level acknowledgements and end-to-end

acknowledgements. This protocol is capable of bulk transfer along a dedicated path, similar to a streaming service. The algorithm awakens the node up to eight times per second to assess the radio channel. Once awakened, the node determines if a preamble is being transmitted. When a preamble is detected, the node prepares to receive data. If the channel is clear, the node may transmit its own data, or retransmit data from another node. The algorithm achieves streaming like quality via messaging to establish a network route and dynamic voltage scaling; an increase in node transmission power to minimize number of hops. [23–24]

The routing techniques of flooding, gossiping and rumor routing were introduced followed by a description of more sophisticated techniques, such as SPIN, GHT, SMCEN and XMesh. This was to facilitate an understanding of the adaptation used when the sensor nodes themselves are the destination, and a directed diffusion routing protocol is employed.

#### **4. Application Layer**

Sensors form the application layer and convert physical phenomenon into transmittable data. A sensor measures a physical quantity and converts this quantity into a physical pulse, which in turn is converted into a binary code and formatted into a data packet. The sensor information in the data packet is transmitted to a designated node, or a base station, depending on the sensor network topology.

#### **D. OTHER NETWORK CHALLENGES**

As sensor networks continue to evolve, explorations into localization, security, energy efficiency, synchronization, and real-time communication remain. Localization is the ability of a node to determine its physical location. The broadcast nature of sensor networks makes them vulnerable to a variety of attacks requiring security techniques as a deterrent. Energy efficiency requires the knowledge necessary to skillfully integrate hardware and software techniques. Node synchronization is important in order to support localization techniques. Real time communications are required in network surveillance applications. [8]

## 1. Localization

Location can be specified globally by the use of Global Positioning System (GPS) satellites, or it can be specified locally by relative position from other devices in the network. This section describes methods to achieve localization through signal processing with an onboard micro-controller rather than GPS. This allows flexibility in number of nodes and sensor composition. To effectively aggregate sensor data, node location should be coupled with sensor information in the message transmitted by each node. A low-power, inexpensive, accurate mechanism is desired. Utilizing a GPS receiver not only adds bulk to the sensor board, but it also consumes high power and does not penetrate dense foliage or buildings. [8]

Indoor localization techniques employ strategically placed fixed beacon nodes. These randomly distributed nodes receive beacon signals and calculate the signal strength, angle of arrival and time difference-of-arrival from different beacon transmitters. Using these measurements, the nodes estimate their position by triangulation or *a priori* knowledge of beacon node locations. [25]

In outdoor situations, or when no fixed infrastructure is available and prior measurements are not practical, some of the nodes themselves act as beacons. In this case, the network requires GPS-enabled nodes to transmit beacon signals. In the case of RF communications, the received signal strength indicator is a method of estimating distance despite its sensitivity to obstacles and environmental conditions. Time difference-of-arrival algorithms can improve accuracy. These localization algorithms estimate location based on a beacon node's location. A direction based localization approach described in [26] assumes that the beacon nodes broadcast to all nodes in the network and that a central controller pivots the beacons at a continuous angular velocity. [8, 25–26]

## 2. Security

The characteristics of wireless sensor networks constrain established techniques for security. Effective security measures require a means of assuring data authentication, data integrity and maintain privacy. Data authentication requires an asymmetric mechanism to avoid message forgery. Data integrity assures that the received data are not altered. [7–8, 20]

Sensor nodes depend on repetitive forwarding by broadcast for message propagation through the network. Selective forwarding attacks are intentional and occur when a node fails to forward packets. A “sinkhole attack” is a form of selective forwarding and occurs where a node falsely advertises the most efficient route. Once the malicious node receives multi-hopped traffic, it begins selective forwarding. Sensor networks are vulnerable to this type of attack because most information is transmitted toward the BS. [8]

The importance of security among networked sensors stems from the significant trust level assumed during data aggregation and event detection. Symmetric or public-key cryptography’s high processing requirements make them unsuitable for many low-power sensor network deployments. If the processing power is supportable, Localized Encryption and Authentication Protocol (LEAP) and Intrusion Tolerant Routing in Wireless Sensor Networks (INSENS) may be employed. [8, 28–31]

Security Protocols for Sensor Networks (SPINS) consist of a number of ideal protocols for extremely resource-constrained sensor networks. SPINS consist of two primary components a sensor network encryption protocol (SNEP) and a micro-version of the timed, efficient, streaming loss-tolerant authentication protocol ( $\mu$ TESLA). SNEP provides data authentication, protection from replay attacks and semantic security at a cost of only eight bytes per message. Semantic security prevents an adversary from determining the plaintext message even after observing multiple encrypted versions of the same plain text by employing a shared counter and incrementing the counter after each block. A replay attack is the introduction of an old alarm message as a current message and is prevented by a counter value carried by the message. Data authentication is verified at the MAC layer. Message integrity and authentication are provided through use of a message authentication code – similar to a checksum derived by applying a secret shared key to the message. [20]

The protocol  $\mu$ TESLA ensures that a broadcast is authenticated, thereby assuring the receiver of the sender’s identity. The protocol allows imprecise time synchronization to exist between the nodes. The BS and each node share knowledge on the maximum synchronization error’s upper bound. Asymmetric cryptographic keys have high over-

head. The protocol  $\mu$ TESLA overcomes this problem by delaying the disclosure of symmetric keys to achieve asymmetry, which provides data authentication. [20]

### **3. Energy Management**

The stringent energy constraint of sensor nodes requires optimization to prolong single node and network lifetime. A node's measure of efficiency is the ratio of data delivered to energy expended. Efficient energy management must be designed into both hardware and software.

Energy efficiency techniques must look to optimize network and node lifetime. The optimization of the hardware level requires employing dynamic power management to each device. Dynamic power management is a technique to shut down node components when no events take place. Dynamic voltage scaling (DVS) is another technique for hardware optimization. Dynamic voltage scaling accounts for the processor's time varying computational load – the voltage is scaled to meet only the instantaneous processor requirements. The operating system, application and network software, should be designed with energy awareness. Voltage is not the only determinant of network lifetime. Considerable energy is consumed by the sleep current of network devices and by the method of routing. [8, 32]

### **4. Synchronization**

Synchronization requires all nodes to agree on time. Synchronization must conform to the low power characteristics of wireless sensor networks to preserve network lifetime.

Node synchronization is required to sustain TDMA schemes on wireless-mesh networks. Synchronization is also necessary to organize messages by time sent from the sensors. Synchronization allows nodes the capability to determine their relative position when deployed randomly. To achieve data aggregation, the sensor must be able to precisely determine the instant in time at which an event occurred in order to recognize duplication. [8]

There are two major categories of synchronization algorithms. The first category achieves long-lasting global synchronization. The second category achieves short-lived, or pulsed synchronization, where nodes are synchronized only for an instant. A low

power synchronization scheme proposed by [33] performs local synchronization by means of a broadcast beacon, from which all nodes normalize their time stamps for observation of the event. This scheme creates short-lived synchronization for nodes within transmission range of the beacon. [8, 33]

A global synchronization protocol described in [34] is based on knowledge of the neighboring nodes control signal. A node leader is elected by majority vote. The leader periodically transmits synchronization messages to its neighbors. These messages are rebroadcast to all networked nodes.

Resynchronization is required in dynamic networks where topology and mobility require synchronization of node clusters to a universal clock. Resynchronization is required in situations such as the merging of two clusters due to mobility. In this case, the clocks of each cluster need to be updated to match the clock of the node chosen as network coordinator. [8, 33]

## **5. Real-Time Communication**

Sensor networks should support real-time communications. The time between sensing an event and communicating the event is a measure of network quality. Real-time communications implies minimal delay experienced in reporting events. The event must efficiently propagate toward the cluster-head or base station. Two protocols that support real-time communication are SPEED and RAP.

The SPEED protocol supports real-time communication in sensor networks by guaranteeing maximum delay. RAP allows applications to concentrate their queries to nodes or portions of the network. The BS or cluster head contains an application layer program that specifies the event information desired, the area to which the query is addressed, and the information reporting deadline. The underlying layers of RAP ensure the communication of the query to all nodes specified in the address and communication of the query results to the BS. [35–36]

## **E. SENSOR CHARACTERISTICS**

Having explored the characteristics of wireless sensor networks and their impact on network architecture and protocols, attention is now turned toward the sensor tech-

nologies. This section describes sensor operation and introduces characteristics of an ideal sensor. The principles governing the operation of an ideal sensor provide a framework for discussion of temperature/humidity, acoustic, magnetic, position, acceleration, light, barometric, and infrared sensors.

Low power, high fidelity and small form factor are desirable features of a sensor. The ideal sensor for networks would therefore have zero mass, zero volume, and infinite bandwidth and require zero signal energy. The zero mass and volume would enhance acceleration and pressure sensors. Infinite bandwidth would improve any sensor, but most useful for video sensors and zero energy requirements remains an unproven ideal. These idealized notions have led research efforts into miniature micro electro-mechanical devices. [37–38]

While not theoretically ideal, modern sensor technologies are relatively small and low power. However, there is a price for miniaturization. As form factor constraints reduce sensor size, operating power densities increase proportionally, resulting in decreased static stability. The decrease in static stability claim is based on comparison with larger and more massive sensor designs. This decrease in stability is a design factor in miniaturization but not a deterrent to miniaturization. [37–38]

Another factor influencing sensor miniaturization is the Heisenberg uncertainty principle, which assures that every sensor is influenced by more than its measured phenomenon. For example, the intent may have been to measure pressure, but the measurement of pressure reflects all aspects of the physical world, such as temperature and humidity. By understanding these interactions, sensor designers are able to improve the quality of measurement. [37–38]

The characteristics of an ideal sensor provide a framework for discussion and description of several specific types of sensors.

### **1. Temperature/Humidity Sensors**

Temperature can be measured by several types of instruments; thermocouples are the most common technique for sensor networks. A thermocouple is a junction of dissimilar metals, which produces a small electromotive force due to the temperature differences. [37]

Relative humidity is the ratio of the actual vapor pressure of the air at any temperature to the maximum of saturation vapor pressure at the same temperature. Relative humidity  $H$  represents vapor content as a percentage of the concentration required to cause the vapor to saturate, i.e., the formation of water droplets (dew) at that temperature. In percent,  $H$  is defined as:

$$H = \frac{P_w}{P_s} \times 100 \quad (2.1)$$

where  $P_w$  the partial pressure of water vapor and  $P_s$  is the pressure of saturated water vapor at a given temperature. [37]

Relative humidity and temperature can be obtained using Sensirion's SHT11 sensor, which allows for relative humidity readings from 0 to 100% with an accuracy of  $\pm 3\%$  using an optical hygrometer. The basic idea of an optical hygrometer is the use of a mirror whose temperature is precisely controlled at the threshold for dew formation. Air is sampled and pumped across the mirror's surface. If the mirror temperature crosses a dew point, it releases moisture in the form of water droplets. The water droplets scatter light rays projected onto the mirror surface. This scattering is detected by a photodetector. The relative humidity can be obtained from the dew point and the prevailing temperature. The temperature is measured by means of a thermocouple; accuracy is  $\pm 5^\circ$  at  $25^\circ\text{C}$ , and the power consumption is rated at  $30 \mu\text{W}$ . [23–39]

## 2. Acoustic Sensor

Acoustic sensors rely upon alternate expansion and compression of sound waves. Whenever sound is produced, air is alternately compressed and rarefied, and these pressure differences propagate outward as sound waves. A general equation for pressure exerted by a sound wave is

$$p = p_m \sin(kx - \omega t) \quad (2.2)$$

where  $p_m$  is the magnitude of the sound pressure,  $k = 2\pi/\lambda$  is a wave number ( $\lambda$  is wavelength), and  $\omega$  is angular frequency. [37]

Pressure levels,  $\Pi$ , can also be expressed in decibels as

$$\Pi[\text{dB}] = 20 \log_{10} \left( \frac{p}{p_0} \right) \quad (2.3)$$

where  $p_0 = 2 \times 10^8 \text{ N/m}^2 = 2 \times 10^9 \text{ psi}$ . This pressure subjects a crystalline piezoelectric material to stress and generates an electric charge proportional to input pressure. [37]

In the National Semiconductor LMC567 Low Power Tone Decoder, the piezo-electric charge produced by the pressure levels of Equation 2.3 provides input to a Voltage-Controlled Oscillator (VCO). The VCO establishes reference signals for phase and amplitude detection. The phase and amplitude detectors are devices that produce a measure of the difference in phase and amplitude, respectively, between an incoming signal and the output of the VCO. As the incoming signal and the output of the VCO change with respect to each other, the difference becomes the time-varying signal. The output of the phase detector is input to the VCO to aid in tracking the incoming signal. The output of the amplitude detector is a measure of the received tone. The device can operate with supply voltage varying from 2 V to 9 V and at input frequencies ranging from 1 Hz to 500 kHz. Low supply current drain is possible through tradeoffs in the resistor and capacitor values of the timing circuit. Additionally, out-of-band signals and noise are rejected. [40–41]

### 3. Magnetic Sensor

One of the many advantages of using magnetic field for sensing position and distance is that the field can penetrate any nonmagnetic material with no loss of position accuracy. The magneto-resistive effect is the ability of a material to change its resistivity in the presence of a magnetic field. This is a well-established property of magnetic material with carrying a current. This change in resistivity is created by the materials' magnetic field rotating relative to current direction. Most conductors' resistivity increases in the presence of a magnetic field. The basic cause of magnetoresistivity is the Lorentz force, which causes electrons to move in curved paths between collisions. The Lorentz force,  $\vec{F}$ , on a moving particle when both electric and magnetic fields are present is given by

$$\vec{F} = q\vec{E} + q\vec{U} \times \vec{B} \quad (2.4)$$

where  $q$  is the charge,  $\vec{E}$  is the electric field,  $\vec{U}$  is the velocity vector of the charged particle and  $\vec{B}$  is the magnetic field strength. [37–42]

Magneto-resistive sensors determine a change in earth's magnetic field due to the presence of a ferromagnetic object or due to change in position within earth's magnetic field. A magneto-resistive sensor is fabricated of permalloy strips (80/20 alloy of Ni and Fe) positioned on an arm of a wheatstone bridge. The degree of the bridge imbalance is then used to indicate the magnetic field strength. Honeywell HMC1002 two-axis magnetic sensor has a field range of  $\pm 6$  gauss. The two-axis sensor can work together to provide three-axis sensing. Configured as a four-element wheatstone bridge, these magneto-resistive sensors convert magnetic fields to a differential output voltage and are capable of sensing magnetic field as low as  $30 \mu\text{gauss}$ . (The Earth's magnetic field is 0.5 gauss.) The sensor reports the magneto-resistive effect in terms of mutual gauss (mgauss). High bandwidth provides the opportunity to detect vehicles and other ferrous objects at high speeds. The sensor's operational range is dependent on the ferromagnetic mass measured. The NiFe permalloy core sensitivity makes it subject to saturation when the sensor is exposed to a large magnetic field. [40, 43]

#### **4. Position Sensor**

Localization is a technique for sensing position where the reliance is on signal processing at the node level. Localization techniques in outdoor scenarios still require a portion of the network to be GPS enabled. GPS is the predominant form of position sensing. The simple GPS receiver stores the pseudo-random code of each of the GPS satellites in memory. By identifying the code, the receiver knows which satellite is sending each signal. Comparing the delay between the receiver's pseudo-random code and that generated by the satellite determines travel time. Multiplying travel time by the speed of light determines distance. By recording these measurements for several satellites, position can be determined by triangulation. GPS satellites employ an atomic clock and predictable orbits to reduce the error. Error information is transmitted along with timing signals. The position is determined from multiple range measurements and computed by the receiver in earth-centered  $X, Y, Z$  coordinates and then converted to latitude, longitude and height. [44]

The small-form factor of the Leadtek GPS 9546 makes them well suited for sensor networks. This GPS provides twelve channels for in-view tracking. It is designed with a Cold/Warm/Hot start time of 45/38/8 seconds with reacquisition in 0.1 seconds. Its accuracy rating is within ten meters when determining latitude and longitude. It is rated to withstand high velocity, acceleration up to 4 g, and altitudes up to 18 kilometers, and its trickle power duty cycle is designed to reduce power consumption to 65 mW. [40, 45]

## 5. Acceleration Sensor

The accelerometer is the primary form of motion sensing (static acceleration). It is designed to measure the rate of change of position, location or displacement of an object. Vibration is dynamic acceleration and a mechanical phenomenon that involves periodic motion around a reference position.

A mathematical model of an accelerometer is represented by

$$x(t) = \int_0^t g(t-\tau)a(\tau)d\tau \quad (2.5)$$

where  $x$  is the instantaneous acceleration at time  $t$ ,  $a$  is the time-dependent impulse of the accelerometer and  $g(t)$  is time-dependent, a delayed version of  $a$ . The equation can be solved for different acceleration inputs applied. The correctly designed accelerometer possesses a clearly identifiable resonant frequency and a flat frequency response at which the most accurate measurement can be made. [37]

By measuring the acceleration, it is easy to determine both the speed and position of the object as well. The Analog Devices ADXL202E Dual Axis Accelerometer provides two-axis acceleration measurements on a single integrated chip. Its form factor is 5 mm × 5 mm × 2 mm and consumes less than 0.6 mA. It will measure accelerations with a full-scale range of ±2 g and has a 1000-g shock survival. The device can measure both dynamic acceleration (vibration) and static acceleration (gravity). The outputs are analog voltages or digital signals whose duty cycle (pulse width/period) is proportional to acceleration, and the device resolution is 2 g at 60 Hz. [40], [46]

## 6. Light Sensor

The process of optical detection involves the direct conversion of optical energy (photons) into an electrical signal (moving electrons). One technique for optical detection is to employ a photodiode. [37]

Photodiodes are semiconductor optical sensors. If a PN-junction is reverse biased (negative side of the battery is connected to the p side) when exposed to light, the current will increase noticeably. Figure 4 depicts a reverse biased PN-junction. Impinging photons create electron-hole pairs on both sides of the junction. When electrons enter the conduction band, they start flowing toward the positive side of the battery. Correspondingly, the created holes flow to the negative terminal, meaning the photocurrent flows in the circuit. [37, 47]

**Figure 4. Illustration of Reverse Biased PN-junction (From Ref. [47].)**

The TAOS TSL2550 combines two photodiodes and a companding analog-to-digital converter on a single chip to provide light measurements to convert light intensity into a digital signal. Both diodes are sensitive to infrared light, and one is sensitive to both infrared and visible light. [40, 48]

## 7. Barometric Sensor

The physics of pressure detection are similar to that of the acoustic sensor. To make a pressure sensor, two essential components are required a plate membrane with a known area and a detector that responds to a known force. Both components can be fabricated in silicon. [37]

A silicon-diaphragm pressure sensor consists of a thin silicon diaphragm as an elastic material and piezoresistive gauge resistors. Because of the properties of single-crystal silicon, the membrane displays elasticity with increased sensitivity, reduced error, and no hysteresis. The MS5534B barometric sensor from Intesema contains a piezoresistive pressure sensor and an ADC-interface. It provides a 16-bit data word from a pressure- and temperature- dependent voltage. The module contains six readable coefficients for calibration accuracy. The device is designed for low power, operates from a supply voltage of 2.2 V to 3.6 V, and is configured for automatic on/off switching. The pressure range is from 0-1100 mbar and the system clock operates at 32.768 kHz. [37, 40, 49]

## **8. Passive Infrared (PIR) Sensor**

A PIR sensing element must be responsive to infrared radiation within a spectral range where most of the power emanated by humans is concentrated (4 to 20  $\mu\text{m}$ ). There are three types of potentially useful sensing elements: thermistors, thermopiles and pyroelectrics. Pyroelectrics are exclusively used in motion detection applications because of they are simple, inexpensive and responsive across a broad dynamic range. [37]

A pyroelectric material generates an electric charge in response to thermal energy flow through its body. The absorbed heat causes the front side of the sensing element to expand. The resulting thermal expansion induces a voltage. Charge can also be induced when subject to an external force, which is often indistinguishable from those produced by thermal energy. Thermally induced charges are separated from external force-induced charges by manufacturing pyroelectric sensors in a symmetrical form. Two elements are connected to the electronic circuit to produce out-of-phase signals when subjected to the same input. [37]

A typical infrared non-contact sensor consists of a sensing element, protective window, support structure, housing and connectors. The sensing element is a component that is sensitive to electromagnetic radiation in the infrared wavelength. The protective window is impermeable to environmental factors and transparent to the wavelength of detection. The operating principle is based on the sequential conversion of thermal radiation into heat, followed by conversion of heat level into an electrical signal. Infrared

sensors produced by Omega offer six infrared spectral responses. They are sensitive across a temperature range of 50° F to 200° F with adjustable response time from 0.2 to 5.0 s. [37, 40, 50]

In this chapter, the characteristics of wireless sensor network were described followed by a detailed description of layered and clustered architectures. The protocol stack for a typical sensor network and the associated functions were discussed. The challenges associated with localization, security, energy management, synchronization, and real-time communication were described. The characteristics of an ideal sensor were introduced followed by a description of several types of sensors. A discussion of the IEEE 802.15 family of standards and the details of the network prototyped in this thesis follows in the next chapter.

### III. NETWORK PROTOTYPE

In designing wireless sensor networks, several of their unique requirements need to be taken into account. Selection of the sensor, or sensors, that meet the application-specific need is the first of them. The radio frequency band in which the network is required to operate and the range of coverage are determined by the terrain and electromagnetic conditions and, therefore, must also be considered. The reader may note that these requirements are in addition to the requirements, such as energy and size, indicated in the previous chapter.

This chapter provides a summary of the IEEE 802.15 family of standards followed by a description of the IEEE 802.15.4 standard. A discussion of network hardware and software is included. The details of the prototyped network are described.

#### A. IEEE 802.15.4 STANDARD FOR LOW RATE PERSONAL AREA NETWORKS

A number of wireless network standards, such as the IEEE 802.11, are available, which in principle can be used for gathering and dissemination of sensor data. Nevertheless, the IEEE 802.15.4 is a standard specifically developed for low-rate sensor networks. This section provides an overview of the various standards designed for wireless personal area networks (WPANs). The current standards in the IEEE 802.15 family are IEEE 802.15.1, IEEE 802.15.3, and IEEE 802.15.4. A discussion of these standards provides a basis for establishing a preferred standard.

IEEE Standard 802.15.1 (Bluetooth) was the first Wireless Personal Area Network (WPAN) standard to be licensed. Its architecture is based upon the slave – master concept and forming of piconets. The modulation technique used is frequency hopping spread spectrum, and the clock of the master synchronizes all slaves to the frequency hopping channel. When multiple piconets overlap, they form a “scatternet”; a Bluetooth device can participate in several piconets at the same time. Channel access is governed by a time division duplexing scheme. [13]

The IEEE Standard 802.15.3 supports *ad hoc* connections, quality of service (QoS), and high speed (up to 55 Mbits per second). The network architecture employs piconets. Piconet Coordinators (PNC) maintain synchronization, supervise QoS and power save modes, and manages authentication. The physical layer operates at 2.4 GHz, and the standard supports six distinct modulation techniques. The MAC layer utilizes CSMA and TDMA to allow the transportation of synchronous and asynchronous data. A beacon sent at the beginning of each frame is used to synchronize the PNC and the network nodes. [13]

The IEEE 802.15.4 standard was developed to support networks of ultra low power at low cost. The network is composed of full function and reduced function nodes. The physical layer operates at 2.4-GHz and 915-MHz bands in the United States. The 915-MHz band operates over ten channels and uses binary phase shift keying modulation. The 2.4-GHz band operates over sixteen channels and uses offset quadrature phase shift keying modulation. The MAC layer uses CSMA/CA for channel access. [51] A detailed description of this standard is provided below.

Many applications require short range wireless connectivity, ultra-low power consumption and low cost. Sensor networks contain thousands of interconnected sensors with a desired battery life of up to several years. With battery life as a key criterion, network designers traded high data rate for long battery life. The IEEE 802.15.1 and IEEE 802.15.3 standards support high data rates but do not offer low power and low cost. Sensor networks are an application of the IEEE 802.15.4 standard. Low-power consumption is a unique requirement of wireless sensor networks. The ability to self-organize and establish reliable communication at low cost are desired characteristics. The network formation, the physical layer and the MAC layer are described in the following section. [13, 51]

## **1. Network Formation**

### ***a. Star Network Topology***

Sensor network topology depends upon the application. The network can self-organize into either a star or peer-to-peer topology. In star topology, as shown in Figure 5(a), a network coordinator governs communication between nodes. The network coordinator, a full function node, initiates or terminates network communications or

routes communication around the network. Once selected, the coordinator allows other nodes to join its network. This is achieved by selecting a unique identifier within the coordinator's sphere of influence and broadcasting this identifier to neighboring nodes. Nodes receive the broadcast and elect to associate with a network coordinator. If the node is within the sphere of influence of multiple coordinators, the node establishes itself within the network by selecting a network identifier and responding to the associated coordinator. [51]

**Figure 5. Star and Peer-to-Peer Topologies. (After Ref. [51].)**

***b. Peer-to-Peer Network and Cluster Establishment***

The peer-to-peer topology, as shown in Figure 5(b), includes a coordinator and is distinct from star topology in that nodes within range can communicate among themselves. Peer-to-peer network nodes organize themselves into various organizations, thus demonstrating the characteristic of self-organization.

The peer-to-peer topology allows multiple hops to route messages between nodes. An example implementation of the peer-to-peer topology is a cluster tree as

shown in Figure 6. In a cluster tree, the network is comprised of mostly full-function nodes. A reduced-function node may connect to the cluster tree as a leaf node at the end of a branch and is restricted from communicating with more than one full-function node at a time. Any full-function node can act as network coordinator, but only one can assume this role. The network coordinator provides synchronization for other devices. The network coordinator forms the first cluster and establishes itself as the cluster head (CH) with a cluster identifier (CID) of zero. The cluster head chooses an unused network identifier. Beacon frames are broadcast to devices within a cluster head's sphere of influence. Nodes receiving the network coordinator's broadcast beacon may request to join. [51]

**Figure 6. Cluster Tree Formation Using Peer-to-Peer Topology. (From Ref. [51].)**

## 2. Physical Layer

The first layer in network architecture is the physical layer (PHY) as shown in Figure 7. Emphasis is placed on techniques for modulating and demodulating sensed data. Physical layer specifications that are universal regardless of the modulation technique are discussed.

**Figure 7. Low Rate Wireless Personal Area Network Architecture. (From Ref. [51].)**

The PHY provides data and management services. The data service enables transmission and reception across the radio channel of PHY Protocol Data Units (PPDUs). The Physical Layer activates and deactivates the transceiver, detects the energy level within the current channel, provides a measure of link quality for received packets, selects the operating frequency and conducts Clear Channel Assessment (CCA) for CSMA-CA. Activating and deactivating the radio transceiver allows for radio communications. When energy is detected, the receiver is activated to determine the destination of the network traffic. Nodes that are the destination or are part of a multi-hop scheme continue to receive and process the message. Energy detection determines if other devices in the network are communicating and provides a method for clear channel assessment. The link quality indicator provides a method to assess the quality of a particular link. [51]

The efficient performance of the PHY is governed by the services it provides. The technique for modulation and demodulation forms the basis for PHY layer operations. The operating frequency bands and data rates of the PHY layer are outlined in Table 1. The method of calculating the center frequency differs based on the device's oper-

ating frequency. Only one channel exists for devices operating at 868.3 MHz. The center frequency for remaining frequency bands is established by:

$$\text{for nodes at 900 MHz } F_c = 906 + 2(k - 1) \text{ for } (k = 1, 2, \dots, 10) \quad (3.1)$$

$$\text{for nodes at 2.4GHz } F_c = 2405 + 5(k - 11) \text{ for } (k = 11, 12, \dots, 26) \quad (3.2)$$

where  $k$  is the channel number.

**Table 1. Frequency bands and Data Rates IEEE 802.15.4 (After Ref. [51].)**

PHY (MHz)	Frequency (MHz)	Spreading Parameters		Data Parameters		
		Chip Rate (kchip/s)	Modulation	Bit Rate	Symbol Rate (ksymbol/s)	Symbols
868	868–868.6	300	BPSK	20	20	Binary
915	902–928	600	BPSK	40	40	Binary
2450	2400–2483.5	2000	OQPSK	250	62.5	16-ary Orthogonal

The receiver characteristics for the 2.4-GHz band specify a sensitivity of  $-85$  dBm or better. The 868-MHz and 915-MHz receivers are designed for receiver sensitivity of  $-92$  dBm or better. The minimum jamming resistance for all channels specifies channel rejection of 0 dB for adjacent channels and 30 dB for alternate channels. The desired signal reception is 3 dB above maximum allowed receiver sensitivity. [13, 51]

The standard provides the specifications on turn-around time, transmission power, link quality indicator (LQI) measurements and clear channel assessment (CCA) for all three frequency bands. Transmit-to-receive and receive-to-transmit turnaround time equals twelve symbol periods and is measured at the air interface from the trailing edge of the last symbol of a received packet until the transmitter is ready to begin the reception of the next packet (transmit-to-receive) or transmit the acknowledgement of the last packet (receive-to-transmit). Transmitters must be designed for at least  $-3$  dBm with

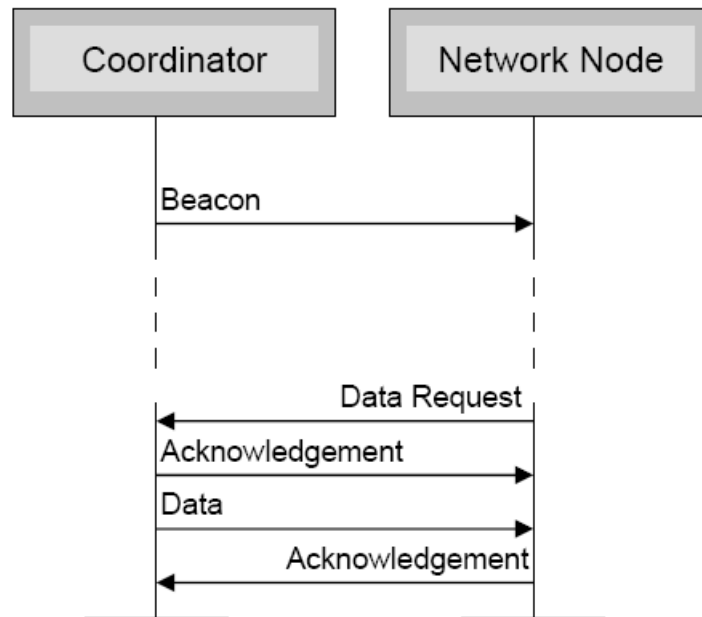

lower power transmission desirable in order to minimize interference. The maximum transmitter power is governed by FCC regulations. The LQI measurements represent the strength and/or quality of the received packet. Link quality may be performed by evaluating the received energy detection, a signal-to-noise ratio estimation, or both. LQI is measured for each received packet and the result is reported to the MAC sub-layer. The highest and lowest link quality values map to the highest and lowest signals identified by the receiver, and values in between should be uniformly distributed with a minimum of eight values between these two limits. The IEEE 802.15.4 PHY provides the means to perform CCA in compliance with at least one of the following three methods: detecting energy above threshold, carrier sense only, and carrier sense with energy above threshold. The carrier sense implementations report a busy channel only when the detected signal's modulation and spreading match those specified in the IEEE 802.15.4 standard. [51]

### **3. Medium Access Control Layer**

The physical layer (PHY) and the Medium Access Control (MAC) layer form the backbone of the 802.15.4 standard. Medium Access Control is based on the Carrier Sense Multiple Access – Collision Avoidance (CSMA-CA) protocol. This section describes the method of CSMA-CA and concludes with an overview of MAC level security services.

In a beacon-enabled network, when a node wishes to transmit data to the coordinator, it first listens for the network beacon. The beacon frame provides information about the permitted packet size, the current network coordinator, the operational state and the length of the contention period. When the beacon frame is found, the device synchronizes to the superframe structure. The node transmits its data frame to the coordinator, using slotted CSMA-CA. [51]

The interaction between a beacon enabled network coordinator and a network node is shown in Figure 8. When data is pending for a networked node, the coordinator uses the network beacon to alert the destination node. The destination node responds with a data request. The coordinator acknowledges the data request and transmits the pending data. The network node acknowledges receipt of the data. [51]

**Figure 8. Communication between Beacon-Enabled Network Coordinator and a Network Node. (After Ref. [51].)**

The different types of frames used in the IEEE 802.15.4 networks are beacon, acknowledgement, and the MAC. The MAC frame format is shown in Figure 9. The MAC frame consists of a header, payload and a two-octet frame check sum (FCS). By virtue of the priority flag in the frame control field of the MAC header, packets can be prioritized in the queue. [13]

The frame control field is two octets long. Within this field, the frame type, address fields and other control flags are specified. The sequence number is used for temporal ordering of frames. The address field contains the unique PAN identifier of the destination and source address. The command payload field varies in length and is data contained is payload specific. The Frame Check Sum (FCS) field is two octets long and containing a Cyclic Redundancy Check to verify error free transmission. [51]

**Figure 9. The IEEE 802.15.4 MAC frame format. (After Ref. [51].)**

In addition to medium access, the MAC layer also implements the security function. The MAC operates in two security modes, access control list (ACL) and secure. The ACL method specifies the nodes with which communication is acceptable, and filters all frames based on the frame's source address. The ACL is also checked for outgoing frames to assure an approved receiving node. The *secure* mode has four security services: access control, data encryption, frame integrity and sequential freshness. Security implementation for IEEE 802.15.4 is similar to that of IEEE 802.11. A combined symmetric encryption and authentication algorithm called CTR+CBC\_MAC is used to provide all four security services. The operations are performed on blocks of data, thereby lending itself well for a parallel implementation. Employment of a symmetric authentication algorithm and block cipher enables input data integrity. [13]

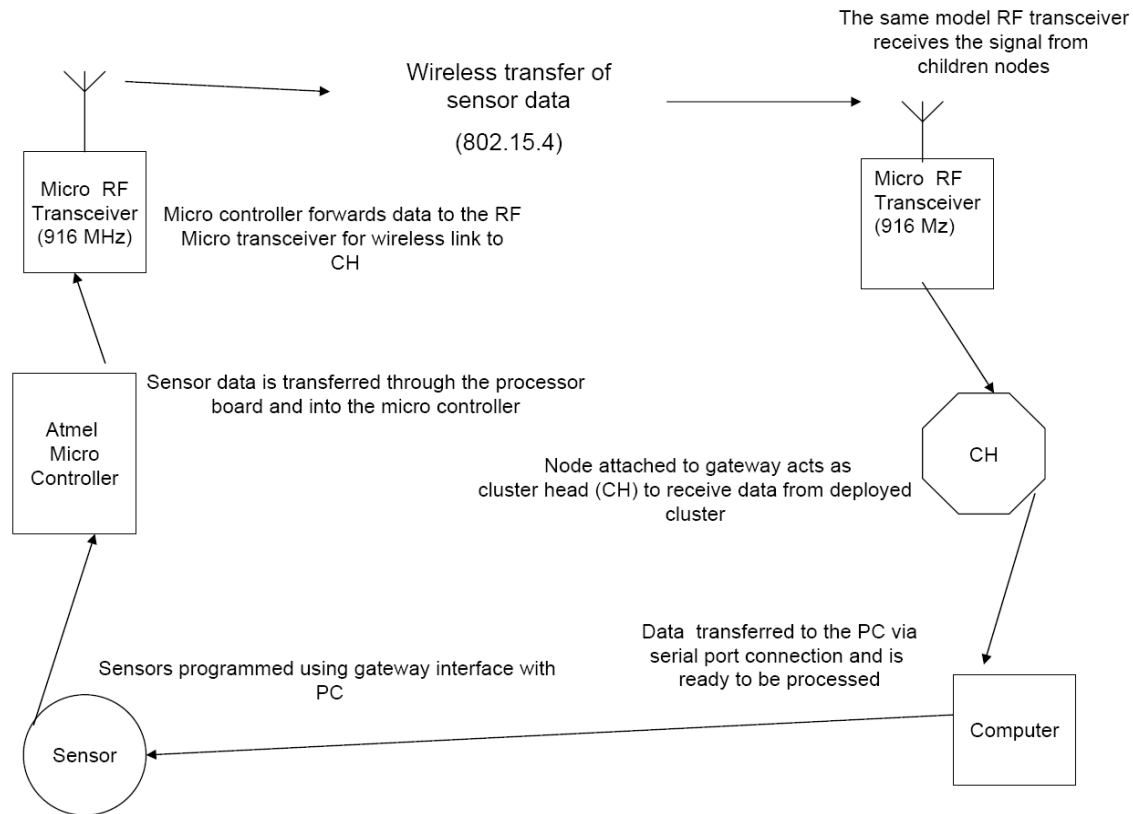

## **B. SENSOR NETWORK COMPONENTS**

The PHY and MAC layer detail the inherent requirements for nodes to communicate in a sensor network. The basic network components are sensors and transceivers. This research employed the Crossbow family of sensors, transceivers and gateways. The industry refers to the nodes as “motes”, and this terminology is adopted here. Motes are an open source hardware and software platform combining sensing, communication and computing into a complete architecture. The hardware design consists of a small low-power radio and processor board known as a mote processor/radio (MPR) and a mote sensor board (MTS), one or more sensors integrated into a single design. The MPR board includes a processor, radio, A/D converter and battery. Many combinations exist for creating MPR and MTS boards. When combined, the two types of boards form a sensor capable of networking. To adhere to the low-power criteria, this combination typically consumes 100 mW while active and 30  $\mu$ W in the idle mode. [40]

The connectivity and functionality of different sensor network components are depicted in Figure 10. The PC programs the sensor either through a gateway interface as depicted or over the air by the Deluge component in TinyOS. The application program runs on the sensors. The sensed data are passed to the microcontroller. The microcon-

troller allows reporting based on time. Another reporting technique is by exception in which the microcontroller only reports events for which a query of interest was cached. [23, 52]

The microcontroller passes the data to the transceiver for wireless communication. After clear channel estimation and recognition, the transceiver forwards the packet to a peer, or the base station, if in radio range. The base station receives the sensed data and forwards them to the computer for further processing and analysis. [52]

**Figure 10. System Block Diagram of a Mica2 Mote (with description of each functional block). (After Ref. [52].)**

### 1. Crossbow Family of Transceivers

These devices follow the IEEE 802.15.4 standard with an additional operating frequency of 433 MHz for the United States Market. A variety of transceivers are designed to allow communication at 915 MHz and 2.4 GHz frequency bands. Device specifics based on operating band are discussed. [53]

The 433-MHz band offers the longest range for the same output power. It has four channels with a 500-kHz spacing. The 915-MHz frequency band operates between 902 MHz and 928 MHz. This band offers forty-eight channels with a 500-kHz bandwidth and 500-kHz spacing between channels. The 2.4-GHz band is acceptable world-wide and has a larger bandwidth. The 2.4-GHz band offers sixteen channels as defined by the IEEE 802.15.4 standard. [23, 53]

The construction and functionality of the motes is dependent upon the frequency band selected. Crossbow's family of motes is recognized by trade names MICA, MICA2, MICA2DOT and MICAz. The subcomponents of the MICA2 mote are detailed in Table 3. All Mica motes utilize the same subcomponents with the exception of the MICAz whose radio is slightly different. A description of the component features follows. The governing principal in mote design is low power i.e., long battery life. A comparison of the specifications and features of mote technologies is given in Table 2. [23, 53]

**Table 2. Specifications of the Four Different Mica Subcomponents. (From Ref. [53].)**

Mote Hardware Platform		MICAz	MICA2	MICA2DOT	MICA
Models (as of August 2004)		MPR2400	MPR400/410/420	MPR500/510/520	MPR300/310
MCU	Chip	ATMega128L			ATMega103L
	Type	7.37 MHz, 8 bit		4 MHz, 8 bit	4 MHz, 8 bit
	Program Memory (kB)	128			
	SRAM (kB)	4			
Sensor Board Interface	Type	51 pin		18 pin	51 pin
	10-Bit ADC	7, 0 V to 3 V input		6, 0 V to 3 V input	7, 0 V to 3 V input
	UART	2		1	2
	Other interfaces	DIO, I2C		DIO	DIO, I2C
RF Transceiver (Radio)	Chip	CC2420	CC1000		TR1000
	Radio Frequency (MHz)	2400	315/433/915		433/915
	Max. Data Rate (kbts/sec)	250	38.4		40
	Antenna Connector	MMCX		PCB solder hole	
Flash Data Logger Memory	Chip	AT45DB014B			
	Connection Type	SPI			
	Size (kB)	512			
Default power source	Type	AA, 2×		Coin (CR2354)	AA, 2×
	Typical capacity (mA-hr)	2000		560	2000
	3.3 V booster	N/A			✓

## 2. Radio

The radio is the most important component of the MPR module. The radio represents the conduit for real-time information. The Crossbow MICA and MICA2 family of motes use a Chipcon CC1000 RF Transceiver. The device is based on the CMOS technology and requires low power for operation. The key features are low power with a transmit current requirements at 9.1 mA for transmission and supply voltage in the range of 2.1 to 3.6 Volts. Other features include a single-chip RF transceiver and programmable frequency of operation. The receiver conforms to the IEEE 802.15.4 standard with a sensitivity of  $-110$  dBm. The transceiver employs PSK modulation with a data rate of up to 76.8 kbps and an integrated bit synchronizer. The transceiver uses dedicated bus architecture to configure radio registers and a dedicated Serial Port Interface (SPI) bus for data transfer. The radio contains no buffering requiring timely bit delivery to the processor. [23, 54]

The Chipcon CC2420 RF Transceiver is used for the MICAz mote. The device is designed to be compliant with IEEE 802.15.4 and meet the specifications of the Zigbee alliance to assure worldwide acceptance in the 2.4-GHz band. By comparing the MICA2 and MICAz motes in Table 2, a comparison of these two chips can be made. The unique features in comparison to the CC1000 are a transmit current consumption at 17.4 mA and a DSSS modem with 2 Mchips/s and 250 kbps data rate. [54]

### **3. Microcontroller**

The Atel ATMega128L microcontroller is used for all Crossbow motes as indicated in Table 3. It employs a 7.3728-MHz clock (4 MHz for MICA2DOT), 128 kB of flash memory, 4 kB of Static Random Access Memory (SRAM) and two UARTs (Universal Asynchronous Receive and Transmit). This device uses an Inter Integrated Circuit (I2C) bus for communication with switches and a SPI bus to communicate with the radio. The device is constrained by 4 kB of memory; this constraint was given special consideration in the development of the operating system. Its advantages over other market devices are the amount of SRAM memory and efficiency in estimating and employing memory. The processor has three sleep modes: idle, off, and power save. Idle shuts the node down, and power save powers down but leaves an asynchronous timer running. The ATMega128L can wake up from sleep in less than 200 milliseconds and, if set to use an internal oscillator, can wake up from sleep in less than 1 microsecond. Its sleep current is 1  $\mu$ A. Power is provided by a 3-V power source, typically two AA batteries. Its operating voltage can be as low as 2.2 V. [23, 55–57]

### **4. Gateways**

Gateways are a means for the network to interact with non-IEEE 802.15.4 compliant devices. They support low-duty-cycle operation for sensor nodes by having the power and functionality for data analysis and storage. This section provides a synopsis of the Crossbow family of gateways. The MIB510 and MIB600 gateways require direct interface with a personal computer. The Stargate gateway is capable of remote interface using 802.11 access. [56]

The MIB510 gateway from Crossbow allows for programming via an RS-232 serial port that it shares with the mote for base station operations. A mote must be connected to the MIB510 to act as network coordinator and forward data outside its area of

coverage. The motes are programmed with node IDs to distinguish their data. The MIB600 gateway allows for multiple operations via an Ethernet port. Remote code debugging can be accomplished over TCP/IP, and the device is capable of powering itself through the Ethernet connection. The MIB510 and MIB600 gateways require a dedicated PC to access and translate the data. [56–57]

For remote operations and when dedicating a PC to a sensor network is unfeasible, Crossbow's Stargate gateway allows for remote access via IEEE 802.11 PCMCIA slot or by connection to a GSM/CDMA cell phone network. This gateway employs LinuxOS. The Stargate provides increased processing power and has expansion slots for additional memory, a PCMCIA card, and for an 802.15.4 transceiver. The Stargate is compatible with all of the Mica motes. The Stargate facilitates remote access data retrieval via TCP/IP connection or cell phone networks. It significantly improves the network scalability. The processing power, form factor and energy constraints are eased to increase functionality. [56–57]

The gateways described are cluster heads that scale to network topology. The cluster heads could establish peering relationships and parent-child relationships.

## **5. Other Components: Memory, Interfaces and Ports**

The other components detailed in Table 3 include memory options, interfaces and port connections. A discussion of these components and their functionality follows.

The MICA2 and MICAz platforms employ 512 kbytes of flash storage attached to the second UART port for over-the-air programming and data logging. The device consumes 15 mA when storing to memory, thus decreasing the battery life. A fifty-one pin expansion connector on the MICA2 and MICAz provides an analog-to-digital conversion interface. The expansion connector provides eight 10-bit analog input/outputs and twenty-one general purpose input/outputs. The connector includes numerous interfaces. Among them are an interface for power and ground, an interface for power control of peripheral sensor, an interface for analog-to-digital conversion of sensor outputs, UART interfaces and an Inter Integrated Circuit (I2C) interface. The motes have a Data Input Output (DIO) interface and a Multimedia Communication Exchange (MMCX) connector for antenna connection. The MICA2DOT's analog-to-digital interface has nineteen pins

with six 10-bit analog input/output ports and six general purpose input/outputs. The MICA2DOT is powered by 3-V lithium coin cell battery, providing a capacity of 560 mA-hrs. [57]

## 6. Sensors

The composition of the sensor subsystem depends on the application. Crossbow motes require the sensor subsystem to connect via a fifty-one pin expansion connector. The sensors detailed in Chapter II are available for mica motes. The MTS310 sensor board with its variety of sensing modalities was deployed for testing in this thesis. This sensor board offers an acceleration sensor, magnetic sensor, acoustic, temperature, and light sensors. It is equipped with a sounder for localization. The MTS 310 is shown in Figure 11. The acceleration sensor and magnetic sensor are highlighted. The acoustic sensor is the button that appears silver with a grey top on the top left corner. The temperature and light sensors are positioned on the left side of the board below the acoustic sensor. [40]

**Figure 11. MTS 310 Sensor Board with Honeywell HMC1002 Magnet-ometer and Analog Devices ADXL202JE Accelerometer. (From Ref. [40].)**

## C. TINYOS ARCHITECTURE BUILT ON NESC

Software components are required to complement the system's hardware components. The software embedded in the sensors represented a considerable portion of the challenge faced by the developers of sensor network devices. Wireless sensor networks' strict application requirements place unique demands on software. The software must be resource conscious by using memory, processor, and power stringently while remaining

agile enough to support simultaneous use of system resources, such as communication and computation. The software to support wireless sensors is a small operating system referred to as Tiny MicroThreading Operating System (TinyOS). The operating system also creates a standard way of developing applications and extending the hardware. Portions of the IEEE 802.15.4 standard combined with TinyOS are the framework for the experimental network used in this thesis. A concise description of TinyOS and its programming language nesC are presented below. [58]

## **1. TinyOS**

Event-based execution is used in TinyOS to provide the desired levels of operating efficiency. The event model allows for high level of concurrency to be managed in a small amount of memory. In TinyOS, all tasks associated with an event are executed rapidly. Hardware events are interrupts, caused by a timer, sensor, or communication device. A task is an execution that runs in the background without disturbing concurrent events. A task can be scheduled at anytime, but execution is always deferred until current pending events are completed. When an event and all tasks are fully processed, the application must declare when they are finished using the processor. This allows the processor to enter a sleep state, rather than remaining active waiting for events. [58]

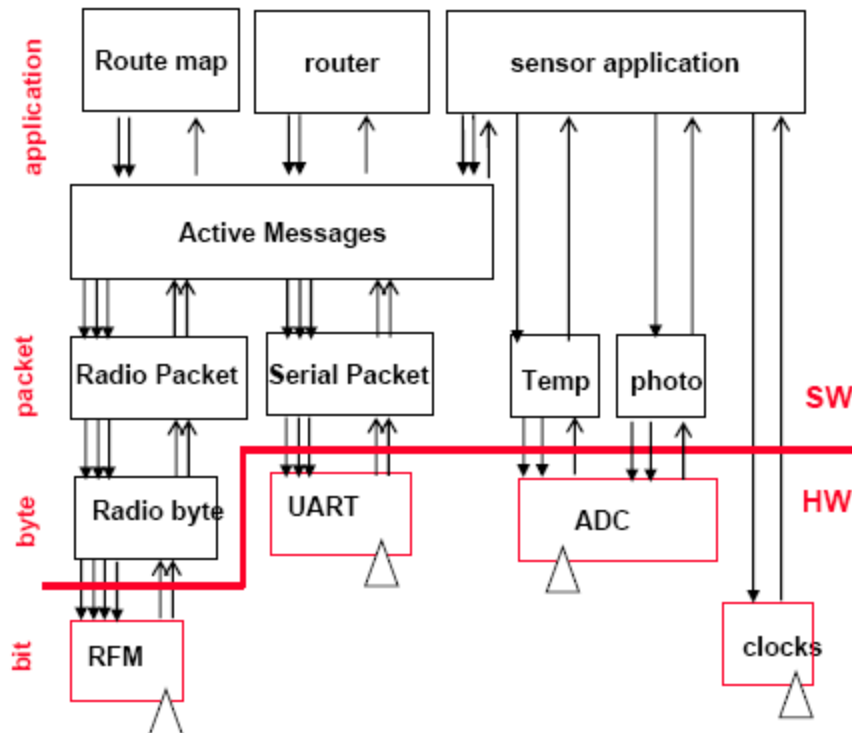

TinyOS system organization consists of a scheduler and *components*. A component must declare the commands it accepts and the commands it uses, as well as the events it signals and the events it handles. Each module has associated commands and events that comprise its interface. Each component declaring the commands it uses and signaling the events it uses facilitates modularity. Higher-level components issue commands to lower-level components, and lower-level components signal events to higher-level components. This allows for wiring of components and allocation of memory based on the application. [5, 58]

Commands cause action to be initiated by a lower-level. Events notify higher level of actions that have occurred. Command/event cycles are avoided by prohibiting commands from signaling events. Both commands and events are intended to perform a small fixed amount of work that occurs within the context of the executing thread. [5, 58]

Because of memory constraints, threads are single sequences of instructions that are called by events. This reduces redundancy within TinyOS thus conserving memory. Threads generate events during execution and calls to command lower-levels. Threads execute quickly and run to completion. [5, 58]

The scheduler is a two-tier, first-in-first-out, queue with a length of seven. The tiers are for events (higher priority) and tasks (lower priority); events cannot stop a task but will preempt a task. [5, 58]

The interaction within a node will be discussed in terms of executing an application. The application will consist of a number of networked nodes within communication range. The nodes monitor temperature and light and periodically transmit their measurements via the network. The network nodes are programmed with routing information and are capable of peer-to-peer routing. The internal components of the described node are shown in Figure 12. [5, 58]

**Figure 12. TinyOS Component Interfaces for a Multihop Sensing Application. (From Ref. [23].)**

The application must service the network and the sensors. Each of these input/output devices is represented by a vertical component stack. The application layer ties the stacks together. An active message contains handler identifiers in each message. The networking layer implements the appropriate handler when the message arrives. This is analogous to events being signaled by the application. Application data are broadcast as a fixed-length active message. If the receiver is an intermediate node between the BS and the destination, the message handler begins retransmission. Once at the BS, the handler forwards the packet for execution. [58]

During execution, a timer event is employed to periodically begin data collection. Once the sensor data are collected, the application employs the **send\_message** command to start a transfer. The **send\_message** command records the message location and schedules a thread to direct the transmission. Upon execution, the thread assembles a packet and starts a chain of commands by calling `TX_byte` within the *Radio Byte* component. This call begins the byte-by-byte transmission. When the byte transmission completes, the *Radio Byte* will transmit the **TX\_bit\_evt** to the packet level controller through the **TX\_byte\_done** event. Once all of a packet's bytes are transmitted, the packet level cues the **TX\_packet\_done** event, which in turn propagates to the application through the **msg\_end\_done** event. [58]

At times when the node is active, but no transmissions are occurring, the *Radio Frequency Modulator* (RFM) component signals the *Radio Byte* component. When a start sequence is detected, the transmission process is reserved. The components convert bits into bytes and bytes into packets. Each component actively signals the higher level. Once a packet is assembled, the address is verified and the appropriate handler is implemented if a local address match is found. [58]

## 2. nesC: a Programming Language for Embedded Systems

The TinyOS system, libraries, and applications are written in nesC, a new language for programming structured component-based applications. The nesC language is primarily intended for embedded systems, such as sensor networks. The syntax of nesC is similar to C, but supports the TinyOS concurrency model, in addition to mechanisms for structuring, naming, and linking together software components into robust network components that can be easily composed into complete, concurrent systems.

#### **D. EXPERIMENTAL NETWORK HIERARCHICAL DESCRIPTION**

A wireless sensor network is an  $n$ -dimensional array of a variety of sensor types and nodes, interconnected by a communications network. Sensor data are shared among the sensors. Sensor networks are predominantly data centric, rather than address centric. Queries are directed to a region containing a cluster of sensors organized by a common coordinator, rather than specific sensor addresses. Aggregation of data can be performed locally, given the similarity of information from a given cluster, which reduces the network bandwidth demands by transmitting fewer packets. A network hierarchy and clustering of sensor nodes allows for network scalability, self-organization, concurrency of operation and lower power. This section describes the combination of the IEEE 802.15.4 standard with hardware and software components for wireless sensor network design. This design was used during experimental and testing phases of this work. [59]

##### **1. Architecture**

The prototype network was organized for peer-to-peer communications. The network coordinator was statically determined and programmed as the node connected to the gateway (see Figure 13). This framework is best described as a peered cluster where nodes can choose a peer (other nodes) to forward transmissions to the gateway (cluster head). The nodes' network identification is preprogrammed. The network consisted of one network coordinator, Node 0, and three sensing nodes, Node 1 through Node 3. All nodes were capable of operating in full function mode and were programmed with the same group identifier. Node 0 is attached to the cluster head.

**Figure 13. Prototype Network Designed for Test and Evaluation**

## **2. Physical Layer**

The network operated on Channel 10 at 908 MHz using CC1010, a combination of CC1000 from Chipcon and an 8051 micro-controller. The link quality was indicated from each child to each parent. The link quality was a function of the number of packets received at the parent versus the number of packets sent. When the child changes parents, the network link statistics were reset, reflecting a change in link quality. The node transceiver operated at 19.2 kbps. The modulation technique used by the nodes is binary phase-shift keying. [23]

## **3. Link Layer**

At the link layer, sensor data were packetized at the micro-controller. Packets received for rebroadcast were handled by the radio and never examined by the micro-controller. Channel access was gained via the CSMA-CA MAC protocol. The network coordinator node transmits a beacon for synchronization. By enabling the beacon, the network was capable of guaranteed time slots; however, this super-frame concept was not employed because of its additional power consumption. [23, 60]

## **4. Network and Transport Layers**

The routing protocol for transmitting data from node to node uses the XMesh algorithm, a descendent of ReliableRoute. The XMesh algorithm was extended, containing

provisions for link acknowledgement, low power and time synchronization [24]. The XMesh message packet has an eight-byte preamble to aid in synchronization, a two-byte synchronizer, and a 36-byte message. [23]

In wireless sensor networks, the traditional transport layer characteristics are not segregated. Connections are established from child to parent and are terminated when an application is complete. Error recovery and flow control are not possible because of a nodes' limited memory, thus end-to-end reliability is not assured. Packets are thirty-six bytes long and segmentation and reassembly are not required. [23]

The final component in the network was a bridge, gateway, or cluster head. The MIB510 gateway from Crossbow functioned as a cluster head and communicated between the network coordinator and the PC. The PC compiled the sensed data for all associated nodes. The cluster head has a serial port connection and connects to a computer through a serial or USB port. The cluster head was capable of supporting data rates of 57.6 kbps. The Stargate gateway, from Crossbow, was also used as a cluster head and enabled remote connection to the wireless sensor network via the IEEE 802.11 PCMICA interface. [56-57]

## **5. Application Layer**

Multiple types of sensors can be integrated into a network of nodes. The Mote Sensor Modules (MTS) used in this network contain various sensor interfaces that are available through a 51-pin connector. This connector links the MTS to the mote processor radio (MPR). The MTS310 Multipurpose Sensor Board from Crossbow was deployed with the motes to form the application layer. The sensors available were magnetic sensor, acceleration sensor, acoustic, temperature, light and a sounder for localization. [40]

## **6. Software Components**

Mote-View provides tools, so the user can visualize the stored results from a wireless network. Mote-View can support a number of firmware applications running on the network of motes. This network design used XMesh to enable XListen, a command line data logging tool, that parses the information received from the motes into user friendly format. Mote-View provides a graphic user interface to aid in data visualization. The nodes were programmed with Surge-Reliable, a network statistics program. Surge-Reliable was used to evaluate radio range. Nodes were reprogrammed with XMTS310, a

program for reporting sensor data. XMTS310 was used to evaluate sensor performance. Mote-View represented the contents of the network's database. The database ran on server software associated with the CPU. The server software listens and records the readings arriving at the base station. These readings are logged to the database for retrieval. [23]

## **E. EXPERIMENTAL PARAMETERS**

There were a number of parameters affecting the designed wireless sensor network. Network and device performances were tested and evaluated in a variety of scenarios. Physical and network parameters were specified for consistency between scenarios. The scenarios varied node elevation in outdoors in open, wooded, and urban environments.

The physical parameters are specified as follows. The node density was limited to one cluster head and three sensor nodes. The transmit power level was +5 dBm (1.64 mW). The antenna chosen was an 80 mm, quarter-wave, omni-directional antenna. Based on the design criteria for a ground sensor network, the node elevation was constrained to ground level, six inches above ground, and twelve inches above ground. Range experiments were conducted for single node and multi node scenarios using non-conductive material as stanchions to elevate the nodes above ground level. When the experiment was designed to measure the range of multiple nodes, the nodes were spaced linearly one meter apart, and distance was incremented from the BS for each node. [23]

The network parameters are specified as follows. As the nodes' distance from the base station was increased, the minimum observation time allowed before evaluating network link quality was two minutes. Link quality was calculated as a ratio of packets received divided by packets transmitted as a measure of successful transmission.

This chapter provided an overview of the IEEE 802.15 family of standards along with a detailed description of IEEE 802.15.4 standard for wireless sensor networks. The issues of network formation, the physical layer, and the MAC layer were discussed followed by a description of network components. The features of the network components available for wireless sensor networks were examined. A discussion of TinyOS, the op-

erating system used for wireless sensor networks, was presented, and an overview of its programming language, nesC was provided. Investigation into the characteristics of a wireless sensor network and the dominant standards has led to an experimental network as described in this chapter. The experimental results from the evaluation of the prototype network follows in the next chapter.

THIS PAGE INTENTIONALLY LEFT BLANK

## IV. EXPERIMENTAL RESULTS

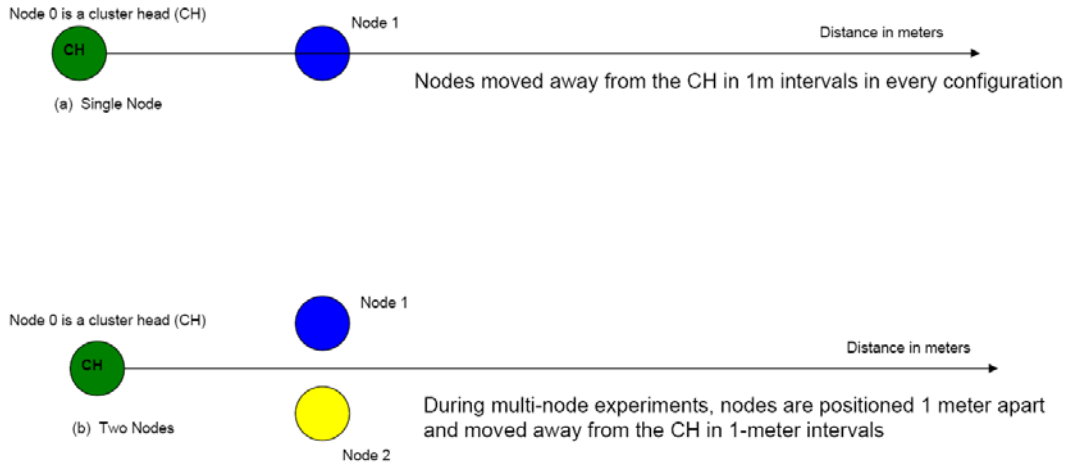

This chapter discusses the results from experiments designed to evaluate the performance of the wireless sensor network described in Chapter III. The experiments are categorized into communication ranges, sensing ranges and network performance. The experimental results were obtained through numerous deployments of MICA2 motes in various scenarios. The radio range was measured indoor and outdoor. The sensing range experiments focused on acoustic, magnetic, and acceleration sensing. Detection and tracking tests were conducted using the acoustic sensor and the magnetic sensor. The network performance was calculated from measurements compiled during the radio range experiments.

### A. RADIO RANGE TEST

Factors influencing the communication capability of a MICA2 mote are transmission power, antenna length, node elevation and effects of multi-path. The radio range experiment focused on the effects of multi-path and the relation to range and node elevation. The transmission power and antenna gain were held constant.

The plots of experimental results depict link quality. Link quality is a ratio of number of packets received divided by number of packets transmitted; specified in the results reported here as a percentage. The plots depict link quality percentage on the y-axis and distance from the cluster head in meters on the x-axis.

Figure 14 describes the physical topology of the network for single node and multi-node experiments. The cluster head, depicted in green, is a gateway device with Node 0 attached. The section begins with the results from open terrain range experiments. These results are followed by results from forested terrain, urban street, and indoor experiments.

**Figure 14. Model of Single and Multi-node Organization for Range Test**

### 1. Open Terrain

These range experiments were conducted in a grass field with virtually no opportunity for multi-path. The grass height was similar to what is expected of an athletic field. No trees, shrubs, or other objects were in the vicinity.

Results from the open terrain range experiment for a single node are shown in Figure 15. The ranges listed are the maximum ranges; beyond this the range communication was not observed. The last recorded link quality at ground level was 98% at four meters. The node at six inches recorded a link quality of 78% at 5.5 meters before losing communication. The node at twelve inches recorded a link quality of 49% at ten meters before losing communication.

The range observations for outdoor open terrain for a network with two nodes are shown in Figure 16. No improvement in range was noticed by offering the opportunity for peer-to-peer communication. (Peer-to-peer communication is an architectural framework for the interconnection of nodes. Nodes within range can communicate among themselves. The peer-to-peer topology allows multiple hops to route messages between nodes.)

At ground level, Node 1's link quality was 54%; Node 2's link quality was 64%. Node 1 and Node 2 when six inches above ground lost communication at five meters with 73% and 78% link quality, respectively.

**Figure 15. Link Quality Versus Range for Single Node Outdoor Open Terrain**

**Figure 16. Link Quality Versus Range for a Two Sensor Node Network in Outdoor Open Terrain**

Nodes at twelve inches maintained communication at ten meters by peering. The link quality of the node communicating with the CH was 67%. For nodes at twelve inches, Node 2 changed its parent at ten meters and began peer-to-peer communication with Node 1. Nodes at ground level and those at six inches remained parented with the CH.

Measurements of network communication ranges were consistent between the single node and the multi-node experiments while the link quality measurements changed. The link quality for nodes at ground level degraded between the single node and the multi-node experiments. This degradation is attributed to radio frequency interference. The nodes at six inches did not experience an appreciable change. The nodes at twelve inches experienced improved link quality at maximum communication range. This is attributed to the nodes establishing a peer-to-peer connection rather than competing for access to the base station.

## **2. Outdoor Wooded**

This scenario was conducted in a wooded area with trees spaced five to eight feet apart. The trees were predominantly pines with trunk diameters of six to eight inches. Pine needles were prevalent on the forest floor as ground cover. The area had small undergrowth vegetation spaced ten to twelve feet apart. The results for single node range test in a wooded environment are shown in Figure 17.

The single-node experiment revealed that nodes at ground level maintained transmission up to five meters with at least 90% link quality, and failed to communicate beyond five meters. The nodes placed at six and twelve inches above the ground maintained communications up to nine meters from the CH; beyond nine meters, reliable communication was not established. At maximum range, the link quality achieved for the node at six inches was 90%, and for the node at twelve inches was 85%.

In comparison to open terrain, the node at ground level's range improved one meter with no appreciable difference in link quality. In comparison to open terrain, the node at the six-inch range improved from 5.5 meters to 9 meters, and link quality improved from 78% to 90%. A node at a twelve-inch range decreased by one meter to nine meters, and the link quality was unchanged.

Multiple-node range performances in a wooded environment are shown in Figure 18. In comparison to a single-node case, the ground range improved by three meters, while link quality degraded 12%. Performance at six inches above the ground remained unchanged with the opportunity for peering. The nodes twelve inches above the ground achieved maximum communication range at twelve meters, a three-meter improvement

over single node measurements. At twelve inches, one of the nodes often experienced unusually high link quality. This resulted from a peer-to-peer association.

**Figure 17. Link Quality Versus Range for a Single Node in Outdoor Wooded Terrain**

**Figure 18. Link Quality Versus Range for Two Nodes in Outdoor Wooded Terrain**

The link quality in open terrain degraded gradually. For wooded terrain, the link quality was somewhat erratic. This can be attributed to more opportunity for multi-path effects of diffusion, absorption, and reflection in a wooded environment. In comparison to open terrain, diffusion and absorption negatively impacted link quality while reflection had a positive impact on range, which improved at each elevation.

### **3. Urban Outdoor**

The urban scenario included many energy-diffusing objects. The urban street was two-lane asphalt with concrete curbs, sidewalks and metal lampposts. It was fronted on one side by a three-story brick building and on the other side by residential homes with foliage bordering the sidewalk. One lane of traffic was blocked off and the nodes were placed in the center of that lane. Vehicle traffic was light and sporadic resulting in no significant enhancement or degradation of range or link quality.

Results for the single-node scenario are shown in Figure 19. At ground level, communication with the CH was lost at three meters. Because of the sharp contrast and departure from previous results, the node was incremented from 3 meters to 3.5 meters. At 3.5 meters, the node's link quality was 89%. This link quality remained consistent at 3.75 meters. The node was unable to communicate with the BS from 4 meters to 5.5 meters. At 5.5 meters the link quality was 63% and the node maintained communication at 6 meters. Beyond six meters, communication was unobserved and attempts were terminated after a range of nine meters. The node at six inches maintained communications until eight meters with last reported link quality of 65%. An interesting result from this scenario is the sharp drop in link quality at two meters. The node at twelve inches lost communication beyond thirteen meters where reported link quality was 58%.

Compared to open and wooded terrain scenarios, the ground level null at three meters was uncharacteristic. At ground level, communication beyond four meters was uncharacteristic. The four-meter range increase at a twelve-inch elevation was also uncharacteristic. These changes can be attributed to the urban environment; absorption and diffusion created electromagnetic nulls, and reflection improved range.

The urban street scenario for two nodes meets with slightly different results compared to the single node case (see Figure 20). The nodes at ground level were able to

configure into a peer network allowing for communications with the CH to be maintained at four meters, but no communication could be maintained beyond four meters.

**Figure 19. Link Quality Versus Range for Single Node Urban Street**

**Figure 20. Link Quality Versus Range for Two Node Network Urban Street**

The nodes at six inches of elevation experienced significant link degradation at five meters. The nodes re-associated in a peering manner, and the link quality improved for Node 1 which peered with Node 2. Node 2's link quality to the CH did not improve. The nodes maintained peered communication with the CH until eight meters where communication for both nodes was lost. Node 1's link quality to its peer was 95%; Node 2's link quality to the CH was 48%. A similar trend was observed for nodes at twelve inches. The nodes peered at seven meters, thus improving the quality of communication for both nodes. The peered relationship was maintained until thirteen meters beyond which communication with the CH was not observed. The link quality for the node at twelve inches communicating with the CH was fifty-eight percent at thirteen meters.

Results demonstrated the diverse effects of the network's environment. Range improvements at twelve inches from the single-node experiment were not observed in the multi-node experiment where results were more consistent with scenarios in open and wooded terrain.

The outdoor urban experiment was repeated with a node multiple of three. The ability for multiple peering opportunities marginally improved range performance at ground level, and no change was observed for nodes at six and twelve inches above ground. Nodes at ground level improved their communication range from four meters to six meters.

#### **4. Indoor**

The experiments for an indoor environment were completed in a two-story banquet room (20' × 60') with two walls of concrete, one wall of glass windows, and one wall of concrete with glass windows. Concrete pillars lined both sides of the room. The floor was tile over concrete.

The results of indoor range experiments for single node are shown in Figure 21. The node at ground level lost communication at three meters with a link quality of 92%. Incrementing by intervals shorter than one meter did not reestablish communication. The node at six inches lost communication at nine meters with a link quality of 74% and, once again, a smaller interval for range increment was unsuccessful in maintaining communications. The node at twelve inches lost communication at ten meters. An increment of

half a meter was attempted and communication was successful. When a range of ten meters from the CH was reattempted, communication was again lost. Placing the node at 10.5 meters resulted in restored communication. The node was incremented in one meter intervals from 10.5 meters. Communication failed at 16.5 meters. Once communication was lost at 16.5 meters, the node was moved to 16 meters and communication was reestablished. The node was again incremented in one meter intervals and maintained communication at a range of 18 meters with link quality of 57%. Beyond eighteen meters, no reliable communication was observed. The more interesting results from this experiment are from the node at twelve inches. In Figure 21, the link degradation at 10 and 16.5 meters can be attributed to absorption and diffusion within the room. The number of reflections in the room improved the maximum range significantly.

The indoor multiple node experiment was conducted using three nodes to increase the opportunity for peering. The nodes were initially deployed in a linear arrangement as shown in Figure 22(a). The results are displayed in Figure 23. The performance of nodes at ground level is similar to the single node case. Beyond four meters, the nodes configure in a peer-to-peer architecture to maintain communication until communication was lost at five meters with 90% link quality. Nodes six inches above the ground began peering at seven meters and maintained this architecture until nine meters with 43% link quality, beyond which communication was not observed. The nodes at twelve inches changed architecture several times until seventeen meters where communication was lost (details of architecture are presented in Section C).

At seventeen meters, the nodes were physically reconfigured from a linear arrangement into a triangular arrangement displayed in Figure 22(b). The distance between nodes was one meter with the node furthest from the CH at 17.5 meters; communication was reestablished. The nodes were aligned linearly at 18 meters, resulting in a loss in communication.

**Figure 21. Link Quality Versus Range for Single Node Indoor**

**Figure 22. Multi-node Arrangement for Urban Street and Indoor Range Experiment (a) Linear Arrangement and (b) Triangular Arrangement**

Adapting the triangular arrangement reestablished and maintained communication until nineteen meters with a link quality of 72% for the node communicating directly to the CH. The dimensions of the room prohibited advancing the range further.

As evidenced by experiments and evaluations, measurements for range and link quality were as diverse as their environments. As expected, the nodes' elevation was the greatest factor affecting performance. While the environments and measurements were diverse, communication at ground level never exceeded six meters and node density had little effect on range. The ranges of nodes at six inches were generally limited to nine meters, and multiple nodes provided marginal improvements. Nodes elevated to twelve inches experienced the most significant variation in range from ten to nineteen meters when given the opportunity for peering

**Figure 23. Link Quality Versus Range for Three Node Network Indoor**

## **B. SENSOR RANGE TEST**

The sensor subsystem was tested for range. Because of the unique aspects of each sensor, specific scenarios were designed based on potential applications. The acoustic, magnetic, and acceleration sensors were selected for testing. The acoustic sensor was tested in a noise-free environment, in an urban market, and outdoors. The magnetic sensor tests attempted to establish parameters for object size relative to distance from the sensor and to monitor vehicular traffic. The acceleration sensor scenario was designed to measure responses to vibration and response to motion.

### **1. Acoustic Sensor**

The test of the acoustic sensor was initially conducted in an indoor area similar to the food court in many shopping centers. The microphone could detect sounds tens of meters away but because of the chaotic nature, reliable estimations of performance were not achieved. The acoustic readings could not be directly attributed to a specific source because of the multitude of competing sounds. The acoustic sensor was then placed in a noise-free room. A news program was played at conversational tone. The sensor node was moved around the room and recordings were documented. The sensors' ability to detect acoustic variations in this environment was restricted to eight meters with a 180° field of view. Beyond eight meters, the human voice was not distinguishable from ambient noise.

A test to determine the suitability of using the acoustic sensor for aircraft tracking was conducted. A sensor field was established approximately one quarter mile from the end of the runway. The sensor field was established in open terrain along the aircrafts' flight path for takeoff and landing. The acoustic signal recorded by one of these sensors is shown in Figure 24; other sensors recorded similar results. The y-axis represents the difference in decibels between ambient noise and measured values. The x-axis represents time scale with each marker representing eight seconds (the time between node transmissions). The three spikes correspond to the aircraft passing overhead after takeoff. The first and second spikes were jet aircraft. The first was a commercial jet and the second a smaller private jet. The third spike corresponds to a twin engine turboprop during takeoff. The first and third aircraft passed approximately 120 feet overhead. The second aircraft passed overhead at a higher but undetermined altitude. The sharp drops after the jet

aircraft passed overhead are attributed to sensor saturation and recalibration. This test demonstrated another application for the acoustic sensor. The sensor field detected and reported aircraft takeoffs. This type of application is a useful early warning system in battlefield scenarios. The system could be deployed for remote monitoring of hostile airfields.

**Figure 24. Acoustic Signal Measured by a Sensor Monitoring an Airport Runway**

## 2. Magnetic Sensor

The magnetic sensor was tested against objects the size of personal and crew-served weapons, as well as vehicles ranging from a sedan to a delivery truck. Successful tests have detected vehicles at a radius of fifteen feet. A test was conducted to determine the sensitivity of the magnetic sensor to battlefield objects. The results are displayed in Table 3. [23]

**Table 3. Magnetometer Sensitivity Readings for Personal Weapons, Crew-Served Weapons, and Automobiles**

<b>Object</b>	<b>Detection Distance in inches</b>	<b>Magnetometer Differential in mutual gauss</b>
Pistol	6	11.61
Rifle	12	11.61
Crew-Served Weapon	16	9.59
Automobile (Sedan)	12	12.8
Automobile (Jeep)	14	33.4
Automobile (Sport Utility Vehicle)	24	76.17

The magnetic sensor successfully detected magnetic field changes for all objects tested. The sensitivity variations in Table 3 reflect the increase in magnetic field reported by the magnetic sensor. These values are measured in mutual gauss and reflect the magnetic field increase in response to the object's presence. As expected, the sensor reading is a function of range and the object's metallic density. The detection distance for weapons is the largest distance at which the sensor reliably detected the presence of the weapon. The magnetic sensor readings for rifle and pistol were identical, but the rifle was detected at a greater distance than the pistol. The same was true for the crew-served weapon. The results indicate a detection range that is extremely short, which implies that this particular model of sensor may not be best suited for this application. A magnetic sensor deployed in a ground sensor network should be able to detect weapons three feet away. Three feet is the approximate height of weapons when personnel are carrying them.

An experiment was conducted to classify the vehicle type based on magnetic sensor readings. The experiment was conducted on a two-lane residential road. The results are displayed in Figure 25 and Table 3. The sensor was placed in the center of one lane

and was driven over by a variety of vehicles traveling at about fifteen miles per hour. The detection distance for the vehicles is the above-ground height of the vehicle chassis. The first object driven through the sensor field was a sedan. The magnetic sensor detected the presence of the vehicle and slowly returned to initial state. The second vehicle was a jeep, which caused the sensor reading to spike indicating vehicle detection. The next object through the sensor field was a sport utility vehicle, which caused the sensor to saturate. The sensor stayed at or near saturation before returning to initial state. The experimental results indicate a magnetic sensor's ability to detect and categorize vehicles by type. Because the sensor seems to differentiate vehicles by type, ground sensor networks could be deployed in battlefield scenarios for vehicle detection.

**Figure 25. Magnetometer Measurements with Vehicle Detections Identified**

The utility of a sensor network arises from the aggregation of data. In some instances, merely combining the results of multiple sensors into a single graphical user interface could provide an opportunity for data fusion. Another instance of data fusion is combining the results of multiple sensors into a single packet of information. A simple test was conducted to fuse network data by overlapping the results from two magnetic sensors. The test was an attempt to demonstrate a wireless, ground sensor network's ability to detect and track.

Two sensor nodes were deployed four meters apart, at ground level, on a residential street. The sensors were left in place during which a variety of automobiles passed over them. The posted speed limit was twenty miles per hour. The results of the magnetic sensor measurements demonstrate the ability to detect and track a metal object (see Figure 26).

Compared to the single node case, inaccuracy and inconsistency were observed. An apparent inaccuracy results from the nodes reporting once every eight seconds; Node 1 reports vehicle detections sixteen seconds earlier than Node 3. Considering the vehicles' speed and the distance between nodes, the sixteen seconds between observations seems inaccurate. An inconsistency exists between the measured values for the sedan and jeep when compared to the results in Figure 25. While time inaccuracy existed and inconsistent measured values were observed, the sensor field successfully detected, reported, and tracked vehicle movement.

**Figure 26. Magnetometer Readings for Two Sensor Nodes During Vehicle Detection and Tracking Test**

### 3. Acceleration Sensor

Attempts to measure the ground vibration using the acceleration sensor were unsuccessful. A sensor field was initially deployed along a residential street with no success. The sensor field was moved and deployed along an eight-lane expressway and measurements taken. The sensors failed to detect any vibration from vehicular traffic. In the case of the residential deployment, the sensor field was one foot from the street. In the case of the expressway deployment, the sensor field was ten meters from the first lane of traffic.

An acceleration sensor's ability to detect acceleration with respect to gravity was tested by mounting the sensors along a vehicle's center line and recording values during city driving. The most dramatic period is shown in Figure 27. The graph reveals an irregular pattern depicting the starts, stops and speed variations experienced while travers-

ing through a city. The positive slopes represent periods of acceleration, and likewise the negative slopes represent periods of deceleration. While this demonstrated a capability of the accelerometer, a more useful application is to detect vibrations. The accelerometer is expected to detect ground vibrations from mechanized vehicles because of the vehicle weight and operation over rough terrain.

**Figure 27. Accelerometer Measurements Under City Driving Conditions**

### C. NETWORK ORGANIZATION

This section describes the network's ability to add nodes and recover from network changes. The time required for the network to add nodes is the time between a node's first attempt to access the channel and the node's first communication within the network. The indoor scenario was used to demonstrate the network's ability to recover from changes since the network reconfigured more frequently than in any other environ-

ment. The network recovery time is the time between network communications resuming and the network routing scheme becoming stabilized.

A sensor network's ability to dynamically self-configure/reconfigure is perhaps its most distinguishing characteristic. Throughout the radio range measurements, the sensors adapted to the irregularities in communication by altering its peered relationship. Peering consists of nodes within range communicating among themselves. The peer-to-peer topology allows multiple hops to route messages between nodes. A parent-child connotation describes the relationship between devices where a parent receives communication from another node, its child. A node can simultaneously be networked as a parent to one node and a child of another.

The network's fastest reorganization time was in forty seconds, which occurred during the urban street scenario when nodes were placed at twelve inches of elevation and one meter away from the cluster head (see Figure 14(b)). Node 1 was in communication with the cluster head, and Node 2 was introduced into the network (see Figure 14(b)). By contrast, in an identical setting when three nodes comprised the network, as show in Figure 22(a), the network required three minutes and twenty-eight seconds to configure and begin communication. In this scenario, Node 1 was in communication with the cluster head and Nodes 2 and 3 were introduced.

The slowest reorganization time was five minutes and forty-four seconds, which occurred during the indoor scenario when nodes were elevated twelve inches and at thirteen meters from the cluster head (see Figure 28(a)). The longest time is not a measure of how long the nodes were out of communication, but rather a measure of the time required for network organization to stabilize routing. During the five minutes and forty-four seconds, the network nodes joined in two minutes and forty seconds, but required an additional three minutes and four seconds to recover and stabilize routing. During this three minute interval, the peering relationship changed as the network self-configured for optimum performance.

The fast and slow reorganization times are the extreme results. The tests and evaluations indicate that the nodes typically join the network within sixty four seconds when placed within one meter of a communicating node. On multiple occasions, com-

munication was lost by incrementing the node's range from the cluster head by one meter. Measurements indicate that on those occasions, recovery times varied between two minutes twenty-four seconds and three minutes and twenty-eight seconds.

Figure 28 displays the network organization and re-association of sensor nodes to maintain communications during the indoor range test. Figure 28(a) shows the node organization observed for the range from one meter to thirteen meters. All nodes were children of the cluster head. Figure 28(b) displays the first re-organization at fourteen meters when Node 1 and Node 3 peered with the Node 2. Node 2 remained a child of the cluster head. The sensor nodes maintained this node organization until fifteen meters. At sixteen meters, Node 3 re-associated with Node 2 while Nodes 1 and 2 remained children of the cluster head (see Figure 28(c)). This organization was short lived. At seventeen meters, communication with the cluster head was lost.

(a) Node Configuration for ranges between 1 and 13 meters

(b) Node Configuration for ranges between 14 and 15 meters and between 18 and 19 meters.

(c) Node Configuration for 16 meters

(d) Node Configuration for 17 meters

**Figure 28. Illustration of Changes in Network Organization During Indoor Range Test**

The physical arrangement of the network was modified into a triangular configuration (see Figure 28(d)), and communication was reestablished. In the triangular arrangement, Node 2 and Node 3 re-associated with Node 1, and Node 1 remained a child of the cluster head. The network topology changed again at eighteen meters as shown in Figure 28(b). This was the network organization through nineteen meters when the physical limitations of room size impeded further testing. Figure 28 graphically depicts the dynamic nature of the child-parent relationship as the network self-configures for optimum performance.

#### D. NETWORK TRAFFIC

The network is characterized by low bit-rate communication because of low power consumption and small-form factor requirements. This low-bit rate characteristic has performance implications governing link utilization, throughput and node density, which are described in this section.

The network bit rate,  $R$ , is fixed based on the physical constraints of the devices. The node's transceiver is configured to operate at 19.2 kbps at 908 MHz. The cluster head used transmits to the personal computer at 57.6 kbps (see Figure 13).

The network's link utilization, node density and throughput are calculated. assuming a transceiver bit rate of  $R = 19.2$  kbps (with no channel coding), a packet length of  $L = 288$  bits, and transmission interval of  $t_{\text{int}} = 8$  s.

The frame length of a packet,  $t_{\text{frame}}$ , defined as the ratio of the number of bits per packet,  $L$ , to the bit rate,  $R$ , is given by

$$t_{\text{frame}} = \frac{L}{R}. \quad (4.1)$$

For this network,  $t_{\text{frame}} = 15$  ms . [14]

The equation for link utilization,  $U$ , the fraction of time transmissions occur on a particular link, is given by

$$U = \frac{t_{\text{frame}}}{t_{\text{int}} - Nt_{\text{frame}}} \quad (4.2)$$

where  $N$  is the number of nodes on a particular link. The link utilization for a single node was  $1.8785 \times 10^{-3}$ . The utilization rate increased modestly to  $1.8856 \times 10^{-3}$  when three sensor nodes were on the same link. [14]

Network throughput,  $T$ , defined as a product of link utilization and bit rate, is given by

$$T = UR. \quad (4.3)$$

For  $R = 19.2$  kbps and  $U = 1.8856 \times 10^{-3}$ , the calculated throughput becomes 36.20 bps or 0.1257 packets per second. [14]

The maximum number of nodes,  $N_{\max}$ , by assuming that the link utilization  $U = 1$ , is given by

$$N_{\max} = \frac{t_{\text{int}} - t_{\text{frame}}}{t_{\text{frame}}}. \quad (4.4)$$

For  $t_{\text{int}} = 8$  s and  $t_{\text{frame}} = 15$  ms, the maximum number of nodes supported by the link is  $N_{\max} = 532$ . For the same bit rate, the number of nodes could be improved by increasing  $t_{\text{int}}$ , which reduces the duty cycle of the transceiver. The lower duty cycle provides an additional benefit of extending network lifetime, by consuming less power. While lower power consumption and increased node density are a benefit of lower duty cycle, the tradeoff is lower data rate per node.

This chapter presented the results from experiments and tests of wireless ground sensor networks. Experiments were conducted to determine node range in a variety of deployment scenarios. Experiments were also conducted to determine the sensing range for the acoustic sensor, magnetic sensor, and acceleration sensor. The results from detection and tracking test using the acoustic sensor and the magnetic sensor were described. Network performance parameters and receiver gain were calculated. Conclusions based on experimental results follow in the next chapter, along with recommendations for future work.

## **V. CONCLUSIONS AND RECOMMENDATIONS**

The development of wireless, unattended ground sensor networks has become feasible with the evolution of integrated circuit technology, wireless communication and networking. Improvements continue to decrease the size and increase their utility. The objectives of this thesis were to prototype a wireless, unattended ground sensor network and to test the node and network performance.

An overview of wireless sensor network characteristics of architecture, protocols and components led to the selection of IEEE 802.15.4 standard and TinyOS as the technologies for prototype development. The network consisted of a cluster of three to four nodes equipped with an acoustic sensor, a magnetic sensor, and an acceleration sensor. The node and network performance parameters were tested and evaluated. Typical communication ranges are four meters for nodes at ground level, ten meters for nodes at six inches above ground, and twelve meters for nodes twelve inches above ground. The sensors' range was dependent on the environment and applications. This thesis substantiated the viability of interconnecting, self-organizing sensor nodes in military applications. The tests and evaluations demonstrated that the network was capable of dynamic adaptation to failure, degradation and tasking.

### **A. CONCLUSIONS**

The range performance of sensor networks was directly proportional to the node elevation and the number of nodes. In a military application, the method of deployment will govern node elevation. Presence of multiple nodes decreased network re-association time and improved the opportunity for peered association, thus improving range performance. A peered association existed when network traffic was multi-hopped to the cluster head. (The traffic is multi-hopped when a node cannot communicate directly with the cluster head.)

Results of sensor-range experiments combined with results from the detection and tracking test established that a sensor node's coverage could be greater than its communication range. Sensing range varied by scenario. Due to these diverse observations in per-

formance, *a priori* knowledge of deployment environment improved the accuracy of node density calculations and network performance estimations.

The characteristics and performance of wireless, unattended ground sensor networks demonstrated their suitability for military applications. The system-level evaluation of device communication and sensing range along with network performance detailed in this thesis provide a method to assess the military applicability of wireless, unattended ground sensor networks.

## **B. RECOMMENDATIONS**

This thesis employed a prototype wireless, unattended ground sensor network. The node range performance measurements were conducted at maximum power with an omni-directional antenna. A recommendation for future research is to evaluate communication range performance for a variety of antennas and power levels. This work would improve network designer's ability to accurately estimate network performance.

A rudimentary fusion of sensor data was achieved by combining the output from two sensors into a single graphical display. The graphical display demonstrated the ability to detect and track objects as they traversed through a sensor field. This method was limited by software tools. A recommendation is to develop software to improve the fusion of sensor data. The cluster head could maintain a database of interest queries and reporting thresholds. The cluster head would only report information matching these criteria fusing the data from several sensors into one report. This is a more elegant software technique and offers the same functionality, reduces the network traffic, and alerts users to significant events

## APPENDIX      INSTALLING TINYOS AND USER INTERFACES

This appendix introduces the procedures for installing TinyOS and some basic commands for programming the nodes.

TinyOS can be downloaded from the TinyOS website (<http://www.tinyos.net/download.html>), through sourceforge's ([http://sourceforge.net/cvs/?group\\_id=28656](http://sourceforge.net/cvs/?group_id=28656)) website, or through vendor distribution. It requires Windows PC (XP or 2000) and 1 GB or more of free disk space in the destination drive. Other requirements are Acrobat PDF Reader and a means to connect from a serial port to the PC. The user must log on with administrator privileges.

1. Pre-Check: Uninstall old TinyOS installations if found and ensure that Java is installed. If Java is not installed, set the path variable to /cygdrive/c/jdk1.4.1-02/bin/java.
2. Install TinyOS from CDROM provided by Crossbow.
  - i. Double click on tinyos-1.1.0-1ls.exe inside the TinyOS install folder.
  - ii. In the “Setup Type” window, select “Complete” and use the default destination folder. Click on “Next.”
  - iii. In the “Java License Agreement” window, click “Yes” and then “Next.”
  - iv. Follow instructions and choose all defaults.

The installation includes:

1. TinyOS and Tools: an event driven OS for wireless sensor networks and tools for debugging.
2. nesC: an extension of the C language designed for TinyOS.
3. Cygwin: a Linux-like environment for Windows.
4. AVR tools: a suite of software development tools for Atmel's AVR processor.

5. Java 1.4 JDK and Java COMM 2.0: for host PC applications and port communications.
6. Graphviz: to view files made from *make* docs.

The installation will create a directory “tinyos” on the C: drive. The applications can be found in C:\tinyos\cygwin\opt\tinyos-1.x\apps.

When installation of TinyOS is complete, verify by opening the *cygwin* window (double clicking on the cygwin desktop icon). Type **toscheck**. The last line should say, “toscheck completed without errors.”

Newer versions of TinyOS are released periodically. The current version and download instructions can be found at <http://www.tinyos.net/scoop/section/Releases>. Copy the update into C:\tinyos\cygwin\tmp\, then open the Cygwin window and type:

```
cd /tmp
```

```
rpm --nodeps --force --ignoreos -Uvh tinyos-1.1.<filename copied>
```

#### **Additional Installation:**

1. Open the cygwin shell and maneuver to the application directory and enter the application of interest. The applications used during this experiment were in contrib/xbow/apps directory of tinyos. These contributions are in a zip file called *xbow.tgz*.
2. Copy the file *xbow.tgz* from the *TinyOS Updates* directory on CDROM to a temporary directory, e.g., C:\tinyos\cygwin\tmp.
3. Open cygwin window and type:

```
cd /tmp
```

```
gunzip xbow.tgz
```

```
cd/opt
```

**tar -xvf /tmp/xbow.tar**

This will unzip Crossbow's contributions to TinyOS. The contributions include network applications and testing tools.

4. Once the file is unzipped, the directory can be accessed. Other contributor's applications are included and can be entered and installed.
5. Install Surge-View by copying the *Surge-View* folder on CDROM to the C:\Program Files\ directory. *Surge-View* graphically captures network level statistics and topology.
6. Install a Mote-View by double clicking on the *MoteViewSetup.exe*. Mote-View is a graphical user interface designed to display application results. Future versions of Mote-View are expected to contain the Surge-Reliable application.
  - a. If the screen Moteview 1.0 setup displaying "The Cygwin release included in TinyOS 1.1 is required but not installed. You will not be able to log data locally. Do you want to continue?" appears, **click YES**.
  - b. The Mote-View setup wizard will start and complete the installation.
  - c. If the system is having problems, manually install the database:
    - i. Open *Cygwin*
    - ii. Type **startdb** to start the database server
    - iii. Type **\q** to quit the database client
    - iv. Type **createdb-task** to generate database tables
    - v. If the problem still persists: **rm -fr /pgdata**  
**createdb-task**
    - vi. Add a local results table by copying *mts310\_db* from the Crossbow cd into c:/tmp and then type:

**psql task <mts310\_db**

Open cygwin and type:

**pg\_dump -f out\_file -t table\_name task**

This sequence will load files into MoteView for data storage.

7. Copy from *Misc* directory on cdrom *pn.exe* and *terminal.exe* to desktop or other convenient location. *pn.exe* is *Programmer's Notepad*, a useful utility for editing tinyos and related files.
8. Add aliases to the bottom of *profile* file at *C:\tinyos\cygwin\etc\profile*:

**alias cdjava="cd c:/tinyos/cygwin/opt/tinyos-1.x/tools/java"**

**alias cdxapps="cd c:/tinyos/cygwin/opt/tinyos-1.x/contrib/xbow/apps"**

**alias cdxbow="cd c:/tinyos/cygwin/opt/tinyos-1.x/contrib/xbow"**

Use these aliases for faster navigation in TinyOS directories.

9. Java Tool compilation is accomplished by first opening *cygwin* window and then typing:

**cdjava**

**make**

Observe the various Java paths as they are being compiled.

10. *XInstall* utility sets up soft links so that commonly used Crossbow programs can run from any directory in Cygwin. To open this utility, in a *cygwin* window, type:

**cd c:/tinyos/cygwin/opt/tinyos-1.x/contrib/xbow/bin./xinstall**

11. Programming Surge-View with the MIB510: Surge-View provides network level statistics of packets sent, packets received, link quality, parent-child relationships, duty cycle, average number of hops from the base node, *et. al.*
  - a. Connect the MIB510 to the serial or USB port of your PC. Check the port number assignment.
  - b. Power MIB with batteries on the mote or with a 5-V power supply. If powering with outlet power, ensure that the power switch on the mote is turned off.

- c. Install mote onto MIB510 using the 51-pin connectors.
- d. Open cygwin window and enter the application directory by typing:

**cdxapps**

**cd Surge\_View**

- e. Type **make** <platform>  
choose device type, i.e., platform [mica2, mica2dot, micaz]
- f. Install the Surge-View program by typing: **make** <platform>  
**mib510,com**<port number of connection> **reinstall**,<node identification number>  
  
\*\*This is the same procedure for installing in program.
  - Use the cygwin window to access the program directory
  - “make” compiles the program
  - “reinstall” installs the programming without recompiling. A time saver when reprogramming multiple nodes
- g. To view the results of *Surge-View*, open a Command Prompt Window and type.

**cd ..\..\Program Files\Surge-View**

- h. SerialForwarder is a Java application to provide a relay between the serial and wireless channels (PC and nodes) using a TCP/IP socket connection.

Start SerialForwarder by typing:

**SerialForwarder –comm serial@COM<#>:57600**

- i. Start Surge GUI by typing:

**Surge <group id> >data\_log**

The data log is optional and provides opportunity for later viewing. The group ID is most easily found by using the *Programmer’s Notepad* and navigating to the **/contrib/xbow/apps** directory. Click on “OPEN” and

scroll down for all files. The *MakeXBowLocal* file should now be visible. This file allows the programmer the ability to change power settings, channels, and ID's. It requires unique settings depending on the type of mote being programmed.

- j. The `data_log` file can be viewed by opening the Surge-View folder in a Command Prompt Window and type: **HistoryViewer <data\_log>** or other file name saved

12. MoteView GUI allows ease of viewing sensor data. The XMTS310 application is found in the `/contrib/xbow/apps/Surge_Reliable` directory. XMTS310 is a sensor application with peer-to-peer routing.

- a. Open a *cywin* bash shell and type **startdb**, or double click on the *PostgreSQL* link on the desktop.
- b. Double click on the Mote-View icon.
- c. Click on the traffic light icon and select: “port number,” “type of device.” Make sure the “log to database” box is checked. Others are optional and add in visualizing the database values.
- d. Select the Connect icon, which is to the right of the traffic light, or select File->Connect. This links Mote-View to the specific database desired. Mote-View provides the capability for viewing “Live” results and maintains a historical archive.
  - i. The server is localhost
  - ii. The port is 5432
  - iii. The default user is tele
  - iv. The default password is tiny
  - v. Click “Connect”
  - vi. Select database = task
  - vii. Table Name = varies depending on application being executed

viii. Client = MoteView

ix. Click “Save” for easy reference and “Apply”
